The major stages of the filamentous bacteriophage life cycle are associated with distinct forms of coat protein. Comparisons among these forms are highly suggestive of the molecular events that accompany the transitions of coat protein and the virus. The results of the NMR experiments on the various forms of fd coat protein are summarized in Figure 5. As shown in the model for procoat protein, the leader sequence has a mobile N-terminus, a structured section, and then a mobile area near the cleavage site. Both procoat protein and the membrane-bound form of coat protein are monomers, since each amide site gives a single resonance in micelles. The features of the model of the membrane-bound form of fd coat protein are similar to those found for the membrane-bound form of Pf1 coat protein,¹⁵ in spite of the absence of sequence homology between these proteins. Both proteins consist of helical secondary structure intermixed with mobile termini and loop regions. The helical regions in fd and Pf1 coat protein consist of two segments, with hydrophobic residues forming a transmembrane helix, and amphipathic residues forming a helix parallel to the bilayer plane. The two proteins differ most in the extent of mobility of the segment connecting the two helices. The connecting loop residues in Pf1 are highly mobile on both slow (10^{-4} s) and fast (10^{-9} s) timescales with an absence of homonuclear ^1H NOE cross peaks involving the

Figure 5 NMR-based models of fd coat protein throughout the viral life cycle

amide resonances for these residues. In contrast, fd coat protein has homonuclear NOE cross peaks throughout the sequence, including the residues involved in the turn connecting the two helices, although there is evidence of limited motional averaging for Tyr-21 — ¹⁶

The structural elements found in the membrane-bound forms of fd and Pf1 coat proteins are similar to those in other membrane proteins, such as bacteriorhodopsin and the photosynthetic reaction center. The dynamic profiles of both coat proteins are also similar to those found in other membrane proteins, since mobile N- and C-terminal residues and a mobile loop connecting rigidly structured helices have been found. The NMR studies show that both fd and Pf1 coat proteins are typical membrane proteins.

Coat protein undergoes minor changes in secondary structure but major changes in tertiary structure upon assembly into the virus particles. A few residues at the C-terminus that are mobile in the membrane-bound form become structural in the virus particles, and some rearrangement of the conformations of the residues in the turn connecting the two helices occurs. However, the protein undergoes a dramatic change in tertiary structure as the two helical segments go from approximately perpendicular, as shown in Figure 5, to approximately collinear in the virus particles. This change demonstrates why there are mobile residues in the turn region between the two helices. This is a very clear example of why it is essential to analyze protein structure and dynamics in concert. It could only have been discovered by NMR spectroscopy.

1 INTRODUCTION

Glycolipids are amphiphilic molecules which are anchored in the cell membrane by a hydrophobic tail. They may be divided, although not exclusively, into two broad categories: those based on diacyl- (or dialkyl-) glycerol [Figure 1(a)], and those based on sphingosine [Figure 1(b)]. Glycoglycerolipids represent the most abundant lipid in nature constituting the dominant membrane lipid in some microorganisms and in plant cells. The relationship between the nature of the glycolipid headgroup and the physical–chemical properties of membranes containing these lipids has been the focus of many studies.¹ It is recognized that biological membranes normally contain lipids that form nonlamellar structures, and that their amounts are actively regulated to maintain proper membrane function. The preference of a lipid to form different aggregate structures (lamellar, hexagonal, etc.) in aqueous dispersions has been related to its ‘molecular shape’ which is intimately connected to the nature and structure of the lipid headgroup (see *Lipid Polymorphism*).²

Glycosphingolipids typically represent minor membrane lipid components, but they play important roles as antibody recognition sites, as toxin receptors, and as elements of cell adhesion.³ This diverse functionality involves biomolecular recognition and, as a result, has motivated structural studies which are directed at defining the conformation(s) of the carbohydrate region.

Since biomolecular recognition of glycolipids takes place within the reference frame of the membrane, the orientation of the lipid headgroup relative to the membrane surface is thought to be important.⁴ Figure 2 compares the isolated glycosphingolipid GM₁ with the molecule in a membrane environment. The important difference between the two systems is that in a membrane the carbohydrate region is proximal to a lipid/water interface. This interfacial environment may have significant impact not only on the carbohydrate conformation but also on how it is presented to the outside world.

2 GLYCOLIPID HEADGROUP STRUCTURE

Given the potential for interplay between membrane environment and the structure–function relationship of these biomolecules, there is widespread interest to probe molecular

Figure 1 Structures of the two classes of glycolipids: (a) X = C glycoglycerolipids (most frequently glucosyl or galactosyl residues) which may have saturated or unsaturated fatty acyl or alkyl chains; (b) glycosphingolipids in which mono- to oligosaccharides are attached to an acylsphingosine residue

Figure 2 Comparison of possible situations for a glycolipid headgroup of GM₁: (a) intact lipid as a monomer as may occur in organic solvents such as dimethyl sulfoxide; (b) lipid embedded in a bilayer membrane. Note that in (b) the headgroup 3D structure is the same as in (a) but is referenced not only to the rest of the lipid molecule but also to the bilayer plane. The orientation of the carbohydrate headgroup [having the same three-dimensional structure in (a) and (b)] relative to the lipid/water interface may influence the recognition process and ‘molecular shape’

structure in macromolecular assemblies, such as lipid bilayer membranes. In general, glycolipids are not readily crystallized and, as a result, the number of X-ray crystallographic studies is small.⁵ For this reason much of the structural information has come from NMR studies. This article will focus on the glycolipid headgroup region. The reader is referred to other articles in this volume for discussion of the acyl chain region (see *Membranes: Deuterium NMR* and *Membrane Lipids of Achleplasma laidlawii*).

2.1 Glycolipid Solution State NMR

Due to their amphiphilic character, glycolipids form micelles or liposomes when they are dispersed in water, which makes high-resolution NMR studies either impractical or of reduced utility in structural studies. This difficulty has been overcome by two approaches that have found frequent use. The first is to cleave the headgroup from the hydrophobic tail and perform conformational studies in aqueous solution. The second approach is to study the lipid in an organic solvent such as dimethyl sulfoxide (DMSO) in which the lipid does not form large aggregates.⁶ Under these conditions, standard high-resolution 1D and 2D NMR techniques for resonance assignment and 3D structure determination have found widespread use.⁷

Much of the glycolipid structural work has focused on glycosphingolipids, in particular gangliosides. Such studies mainly rely on the nuclear Overhauser effect (NOE) to obtain the spatial proximities between protons. This distance map is used in conjunction with molecular mechanics or dynamics calculations to deduce headgroup conformation. However, unlike proteins and oligonucleotides,⁸ oligosaccharides frequently show very few structurally relevant NOE constraints so that three-dimensional structure analysis is dominated by theoretical calculations. Recently, Dabrowski and co-workers have shown that in DMSO protons of hydroxyl and amido groups may be used to obtain additional NOE contacts and thereby extend the experimental basis with which to verify theoretically calculated conformations.^{5,9} The latter approach has been used with the glycolipids globoside⁵ and with gangliosides.^{9–13}

Internal flexibility in glycolipid headgroups indicates that there is an ensemble of structures present. Both ¹H and ¹³C relaxation studies have been used to probe for carbohydrate segmental motion.^{6,10} Although a number of studies have shown that the oligosaccharide is relatively rigid, some oligosaccharides appear to have limited motion about the glycosidic bonds. Recent ¹H $T_{1\rho}$ measurements have shown a pronounced flexibility in globoside and in the ganglioside GM₃.^{5,10}

In a few studies the natural cell surface environment has been approached by incorporating glycolipids at low concentration in aqueous mixed micelles of dodecylphosphocholine under which conditions solution state NMR techniques are still viable. Little difference was seen between solution and micelle associated headgroup conformations.^{9,10}

2.2 Membrane Glycolipid Headgroup Conformation and Orientation

While isotropic solution and micelle studies provide insight into the 3D structural preferences of isolated glycolipids, the results may not be transferable to the membrane situation. Molecular mechanics calculations have shown that in a bilayer arrangement the range of possible conformations is considerably reduced.^{14,15} NMR studies of glycolipids in lipid bilayer environments probe more directly the influence of the membrane environment on carbohydrate structure, surface presentation, and dynamics.

Above the gel to liquid crystal phase transition temperatures, aqueous lipid systems behave spectroscopically as uniaxial

nematic liquid crystals. Thus they represent partially ordered systems, wherein molecular motion is anisotropic covering timescales from picoseconds to seconds. NMR spectra of such systems are dominated by tensorial spin interactions which are only partially averaged. The strategies for structural and motional studies in such systems are similar to those used for organic liquid crystals.¹⁶

To date, ¹³C–¹³C and ¹³C–¹H dipolar and ²H quadrupolar interactions have been used successfully to probe glycolipid systems. In lipid bilayer systems the dipolar and quadrupolar spectral splittings are given by:

$$\Delta\nu = \Lambda \cdot [A_{zz}S_{zz} + 1/3(A_{xx} - A_{yy})(S_{xx} - S_{yy}) + 4/3A_{xy}S_{xy} + 4/3A_{xz}S_{xz} + 4/3A_{yz}S_{yz}] \quad (1)$$

where

$$\Lambda = 3/2 \cdot \chi \cdot 3(\cos^2 \beta - 1)/2 \quad (\text{quadrupolar}) \quad (2)$$

or

$$\Lambda = -\gamma_1\gamma_2/\pi^2 r_{12}^3 \cdot 3(\cos^2 \beta - 1)/2 \quad (\text{dipolar}) \quad (3)$$

and

$$A_{p,q} = (3 \cos \alpha_p \cos \alpha_q - \delta_{pq})/2 \quad (4)$$

and

$$S_{p,q} = \langle 3 \cos \theta_p \cos \theta_q - \delta_{pq} \rangle / 2 \quad (5)$$

The angle β is the angle the bilayer normal makes with the magnetic field direction. The $\cos \alpha_p$ terms are the direction cosines defining the orientation of the C–²H bond direction (quadrupolar interaction) or of the internuclear vector (dipolar interaction, where here the internuclear distance, r_{12} , is not conformation-dependent) to a molecule-fixed frame, and the $S_{p,q}$ terms are orientational order parameters describing the average orientation of the molecular axes p, q with respect to the director of motional averaging, the bilayer normal. The $S_{p,q}$ terms are the elements of a 3×3 order matrix having five independent elements. The order matrix may be diagonalized to give the principal axes of order in the molecular frame. The latter transformation establishes the average orientation of the molecular frame relative to the bilayer normal. If there were no reorientation of the molecule away from the membrane director, then S_{zz} would have a value of 1.0 (completely ordered). If the molecule reorients isotropically about the bilayer normal, then the lipid shows no orientational order and S_{zz} would be 0. Inspection of equations (1)–(5) reveals that the quadrupolar and dipolar splittings depend upon the orientation of the labeled molecular segment through the geometric terms $\alpha_{p,q}$. Structure determination is essentially a matter of obtaining enough geometric constraints to define the structure. For a rigid deuterated or ¹³C-labeled sugar ring, each C–²H bond, ¹³C–¹³C or ¹H–¹³C internuclear vector in the ring has a well-defined orientation within the molecular frame and all sites in the residue have the same order parameters. Thus labeling the carbohydrate with ²H or ¹³C at several positions allows one to determine $\alpha_{p,q}$ for each site, which may be used to define the average orientation of the sugar

ring, relative to the bilayer normal. If orientational ordering is axially symmetric then equation (1) reduces to:

$$\Delta\nu = \Lambda \cdot [(3 \cos^2 \alpha_{zz} - 1)/2] \cdot S_{zz} \quad (6)$$

and at least three quadrupolar (or dipolar) splittings are required (i.e. three or more labeled positions). In general, at least five splittings are required to determine the order matrix and the geometrical terms. To determine the 3D structure of an oligosaccharide chain having no internal flexibility (on the timescale shorter than ms) about the interresidue glycosidic linkages, spin interactions for as many sites as possible need to be measured, preferably at least three splittings for each residue.

A similar strategy has been exploited for peptide structure determination in solid state and membrane samples.^{17,18} Structure determination requires a search over all possible structures wherein direction cosines for the ^2H -C bonds (and/or internuclear dipolar vectors in the molecular frame) and an order matrix (reflecting the restriction of orientational averaging) best fit the NMR results. This is analogous to methods of high-resolution NMR structure determination in which distance constraints obtained from NOE measurements and geometry derived from scalar couplings help to define structure. The two approaches differ in that unlike solution studies, the membrane related 3D structures are spatially referenced to the molecular environment which is the membrane plane. It is this latter aspect that is important in a discussion of recognition-site presentation.

It has been possible to study biological membranes containing glycolipids with isotopically labeled acyl chains by NMR.¹⁹ The difficulty in introducing isotopic labels specifically into glycolipid headgroups in biological membranes has necessitated the use of model membrane systems to examine specific features of interest. Two approaches to modeling the bilayer membrane environment have been used for such NMR studies. The first uses multilamellar liposomes formed by dispersing lipids or lipid mixtures in water or buffer. Such systems give rise to 'powder spectra' such as shown in Figure 3(a) and have been shown to reproduce NMR spectral characteristics obtained with intact biological membranes. The second approach uses glycolipids incorporated into micelle-forming lipid mixtures that orient in the magnetic field²⁰ which give rise to spectra such as shown in Figure 3(b). Spectroscopy in such systems shares strong similarities with that in nematic liquid crystals for which there is a vast literature.¹⁶ These micellar systems may be a poorer model of bilayer membranes than liposomes but they have proven to be useful.

2.2.1 Multilamellar Liposomes

The first use of ^2H NMR to determine the surface orientation of a membrane glycolipid headgroup was reported by Skarjune and Oldfield for galactosylceramide in a phospholipid membrane.²¹ The surface orientation of the monosaccharide headgroup was sensitive to the type of phospholipid present and to other membrane components. A series of simple glyco-glycerolipids have been studied to investigate systematically the dependence of glycolipid headgroup orientation on the carbohydrate moiety. A comparison of three lipids having α -glucosyl, β -glucosyl (β -DTGL), and α -mannosyl residues

Figure 3 ^2H NMR of the glycolipid DTLL in: (a) multilamellar liposomes randomly dispersed (β is random, powder spectrum) with respect to the magnetic field direction (from Renou et al.²⁵ with permission); (b) discoidal micelles (sodium glycocholate-dipalmitoylphosphatidylcholine) which are oriented (oriented spectrum) with the micelle surface at 90° ($\beta = 90^\circ$) relative to the magnetic field

attached to a dialkylglycerol anchor showed that both head-group orientation and ordering were very sensitive to the nature of the carbohydrate residue.^{22,23} A typical ^2H NMR spectrum of β -DTGL labeled at several positions in the glucose ring is shown in Figure 4(a). Position-dependent splittings are readily seen with resonance assignments made by controlling the degree to which each position was labeled. In these studies it was assumed that orientational ordering was axially symmetric and equation (6) was used to extract the order parameter and orientational information from the ^2H quadrupolar splittings. Headgroup order parameters ranged from 0.45 to 0.8 for the three glycolipids. Since dialkyl- and diacylglycerolipids constitute major components of membranes in plants and a number of microorganisms, the three lipids served as a means of examining how glycolipid headgroup properties influence the biophysical properties of membranes. In the case of the lipid β -DTGL, both the headgroup and the glycerol were labeled. Analysis of the glycerol segment alone gave an order parameter of 0.65 whereas that of the glucose ring was 0.45, indicating the presence of segmental motion about the glucose-glycerol linkage. The average structure and bilayer orientation of the glucose-glycerol segment was determined as shown in Figure 5 (left).²⁴ Interestingly, β -DTGL was found to

Figure 4 Typical ^2H NMR spectra of the glycolipid β -DTGL: (a) in the lamellar (bilayer) phase; (b) inverted hexagonal phase. The lipid has been ^2H -labeled to differing degrees at the indicated sugar ring positions. Note that each position gives rise to a separate quadrupolar splitting indicative of the site dependent geometric (structural) terms α_p in equation (4). (From Jarrell et al.²² with permission)

Figure 5 Average structure and orientation of (left) the glucosyl-glycerol region of the glycolipid β -DTGL in a bilayer lipid membrane as determined by ^2H NMR (from Jarrell et al.²⁴ with permission). Note that since the structure is not rigid, there is some motion about the glycosidic linkage, i.e. there is conformational equilibrium representing a range of ϕ , ψ , and ω angles; (right) the lactosyl residue in the membrane-associated glycolipid DTLL, where the headgroup is presented with the average orientation relative to the surface as determined by ^2H NMR (from Renou et al.²⁵ with permission). The membrane surface extends into and out of the plane of the page, and the views are shown along the membrane surface

have a headgroup orientation and orientational ordering similar to that of galactosylceramide, with the sugar ring essentially fully extended away from the membrane surface into the aqueous medium.

Hydrated lipids may exhibit phase polymorphism when the temperature is varied. Aqueous dispersions of pure β -DTGL above its gel to liquid crystalline transition temperature (52°C) form bilayer structures, which on heating to 56°C form an inverted hexagonal structure. This phase transition leads to dramatic NMR spectral changes such as are shown in Figure 4(b). The formation of nonlamellar phases is a result of the small surface area occupied by the lipid headgroup, arising from its surface orientation and relatively high ordering. The headgroup orientation of lipid in a bilayer structure was shown to differ significantly from that of lipid in the hexagonal phase. Such studies indicate that it is now possible to evaluate more rigorously the suggestion that lipid ‘molecular shape’ influences the physical-chemical properties of biological membranes.¹

^2H NMR studies of disaccharide glycolipids have been reported.^{25,26} A dialkylglycoglycerolipid, DTLL, containing the lactosyl ($\text{Gal}_\beta(1 \rightarrow 4)\text{Glc}_\alpha$) residue was ^2H -labeled in each of the two sugar rings affording six quadrupolar splittings and thus six geometrical structural constraints.²⁵ ^2H longitudinal relaxation measurements showed that there was no motion about the galactose-glucose glycosidic linkage, suggesting a relatively rigid headgroup. The ^2H quadrupolar splittings were analyzed according to equation (1) to obtain the order matrix and the disaccharide orientation. Since the signs of the quadrupolar splittings were not known and the splitting values depend upon geometric terms having the functional form in equation (4), a number of headgroup conformations were consistent with the geometric constraints. To evaluate further the structures that were consistent with the NMR data required additional information obtained from conformational potential energy calculations. A search over all possible conformations for the NMR-consistent lactolipid structures gave the lowest energy structure, shown in Figure 5 (right). This structure differs considerably from that of crystalline lactose and that of methyl lactoside in solution, suggesting

that the membrane surface has an influence on the headgroup structure. The headgroup on average was determined to be extended away from the surface and as having nearly axially symmetric ordering with an order parameter of 0.51.

The glycolipid systems studied in detail to date are relatively simple, but such studies demonstrate the potential of the experimental approach. Recently, studies on more complex glycosphingolipids have been initiated. EPR spin label studies have suggested that the oligosaccharide chains of gangliosides in membranes exhibit substantial motion, possibly as a result of segmental motion within the carbohydrate moiety.²⁷ A ^2H NMR study of the ganglioside GM_1 (Figure 2), labeled in the terminal galactosyl residue and incorporated into phospholipid liposomes, has revealed substantial motional restriction.²⁸ GM_1 (five sugar residues) exhibited orientational ordering similar to that of the monosaccharide lipid galactosylceramide, indicating that if there is segmental motion in the oligosaccharide chain it must be of small amplitude.

2.2.2 Molecular Modeling and Liposomal NMR Data

Structure prediction via molecular mechanics/dynamics procedures is a frequently used approach in evaluating the range of conformational structures that a molecule may have. Such methods have found widespread use in carbohydrate structure analysis.⁶ For membrane-associated glycolipids these calculations offer a means of gaining insight into segmental fluctuations in the headgroup region. In comparison with prediction in isotropic solution, the methodology for molecules at membrane surfaces is not as well developed.

The surface-bound blood group A-active glycosphingolipids¹⁴ and a disaccharide lipid²⁵ have been modeled by a modified HSEA (Hard Sphere ExoAnomeric) analysis in which conformations were discarded if any part of the headgroup protruded below the membrane surface. Prestegard and co-workers have used an NMR pseudoenergy approach with AMBER in which ^2H quadrupolar and ^{13}C dipolar splitting data were used as a pseudoenergy term which directed the conformational energy minimization calculations to identify the favored conformation of membrane surface glycolipid analogs in oriented systems.^{20,29–31}

A somewhat different approach has been used with the glycolipid β -DTGL where PFOS (Potential Functions of OligoSaccharides) conformational energy calculations were used to evaluate the conformational potential energy over the ϕ , ψ , and ω angles [see Figure 5 (left) for definitions of the angles ϕ , ψ , and ω].³² The membrane situation was modeled by surrounding a central β -DTGL molecule with an annulus of six static lipid molecules with the distance r between the central molecule and the surrounding lipids as a variable. The sensitivity of the structure to the local environment is seen in a comparison of the ϕ , ψ energy contours for the membrane-embedded molecule [$r = 9.5 \text{ \AA}$, Figure 6 (top)] with that of the isolated molecule [Figure 6 (bottom)]. Such maps clearly show the most likely range of conformational fluctuations that the ‘averaged glycolipid headgroup structure’ can undergo.

The conformations that are potentially allowed for the isolated molecule have a very broad distribution in comparison with those of the membrane-associated molecule. Such theoretical calculations were linked with experiment by estimating quadrupolar splitting values by a Boltzmann-weighted average of quadrupolar splittings calculated for the

Figure 6 Influence of headgroup surface area on conformational energy. Conformational energy as a function of the angles ϕ and ψ for the β -DTGL analog molecule surrounded by an annulus of six surface analog molecules at a distance of (top) 9.5 Å and (bottom) molecule in vacuo. There are 10 contours, each contour is 4.18 kJ mol⁻¹; X represents the global minimum. (From Winsborrow et al.³² with permission)

glucose deuterons (²H-1, ²H-2, ³H-3, and ²H-4) of β -DTGL for each ϕ , ψ , ω conformation. The calculated ²H NMR quadrupolar splittings were found to agree well with those observed experimentally, within the range of intermolecular separations from 9.5 to 10.5 Å (Table 1). The intermolecular separations which gave the best fit were in good agreement with those values determined from monolayer and calorimetric studies which estimated the cross-sectional area occupied by β -DTGL in the liquid crystalline phase to be 102 ± 4 Å² per molecule, giving an intermolecular separation of about 11 Å.³³ In cases where there is evidence of headgroup flexibility, such calculations appear to offer some insight into the degree of conformational averaging involved in the ‘average structure’ and in the segmental order parameters.

Table 1 Experimental and Calculated ²H Quadrupolar Splittings for β -DTGL Glucose Headgroups for Different Surface Constraints

	Glucose deuteron quadrupolar splittings (kHz)	
	Experimental	Calculated ^a ($r = 9.34-10$ Å)
² H-1	22.9	20.1–25.1
² H-2	22.8	17.7–23.9
² H-3	24.0	20.5–26.6
² H-4	26.0	21.4–33.3

^aWeighted average of splittings calculated for each allowed ϕ , ψ , ω combination [Figure 6 (top)].³²

2.2.3 Oriented Micelles

An alternative to multilamellar systems which give rise to powder NMR spectra are micellar systems that orient in the magnetic field. Such systems have a single (or a very narrow distribution of) bilayer orientation, β in equation (1), and give NMR spectra of higher resolution than is achievable with unoriented samples. They also generally require less labeled material than liposomal systems. This is illustrated in Figure 3(b) which compares spectra of the disaccharide lipid, DTLL, in a liposomal system and in oriented micelles. In addition to ²H NMR studies, such systems are amenable to measuring ¹³C–¹³C and ¹³C–¹H dipolar couplings for ¹³C-labeled glycolipids. Prestegard and co-workers have exploited such systems to elucidate the structure of a glycolipid as well as of glycolipid analogs by ²H and ¹³C NMR techniques.^{20,29–31} In these studies, a molecular mechanics program appropriately modified for carbohydrates was used to calculate minimum energy structures, and the NMR data were added as a pseudoenergy term to the empirical description of molecular energies. The NMR data guided the structure calculations amongst a potentially large number of structures having similar energies. Using this approach, Prestegard and co-workers have deduced the average membrane orientation of the sialic acid residue of GM₃ and presented a model of the binding of the sphingolipid GM₃ to wheat germ agglutinin as shown in Figure 7.³¹ Of particular interest in this study is that the sialyl residue’s orientational order parameter S_{33} was found to be 0.73. This order parameter has a value comparable with molecular order parameters reported for other glycolipids and for phospholipids, suggesting that the entire GM₃ molecule may be fluctuating essentially as a single unit. This is particularly interesting since a solution NMR study of GM₃ concluded that a marked flexibility existed for the carbohydrate region.¹⁰

3 GLYCOLIPID DYNAMICS

In solution, it has become increasingly important to probe internal molecular dynamics in order to assess whether a molecular structure is unique or, in fact, an equilibrium of closely related structures. This is also true for membrane associated molecules where an ‘average structure’ may be elucidated. The presence of a hierarchy of internal or segmental motion is frequently encountered with lipid systems. This is true of glycolipids and has led to a number of studies directed toward characterizing the nature and timescales of molecular motion.

Figure 7 Model of membrane-bound GM₃ bound to wheat germ agglutinin (WGA). The 3D membrane structure and orientation of GM₃ was calculated from ¹³C–¹³C and ¹H–¹³C dipolar splittings in oriented micelles. (From Aubin et al.³¹ with permission)

3.1 Elucidating the Types and Rates of Molecular Motion—General Considerations

Deuterium NMR lineshape and relaxation time analysis has become the technique of choice for probing dynamic disorder and molecular mobility in these systems. Through such measurements, molecular dynamics can be followed over at least 10 decades in motional frequencies in a range (10^0 – 10^{10} Hz) where molecular motions in lipid bilayers are concentrated. Lineshape analysis of quadrupolar echo spectra provides information on the rates and mechanism of reorientation in the range of 10^3 – 10^6 Hz. Access to shorter timescales is provided by longitudinal relaxation measurements which probe motions occurring on the timescale of the Larmor frequency (10^8 – 10^{12} Hz). Studies of glycolipid motion have exploited the two longitudinal relaxation times, T_{1Z} and T_{1Q} , and their differing dependences on the orientation of the bilayer normal with respect to the magnetic field (T_1 anisotropy). Since the T_1 anisotropy is sensitive to both the rate and type of motion, it affords a powerful means of distinguishing between physically reasonable motional descriptions. Such measurements augment the usual studies of temperature and magnetic field strength dependence of T_1 . The application of anisotropic relaxation has found extensive use with protein systems but has only recently been exploited in lipid membranes.³⁴ Unambiguous measurement of relaxation anisotropies have been best made by aligning the bilayers of model lipid membranes between glass plates, which can then be precisely oriented within the magnetic field.³⁴ Measurement of the dependence of relaxation rates on sample orientation maps out the orientation dependence. Longer timescales are accessible through two-dimensional chemical exchange experiments which extend the frequency range to include motions $<10^3$ Hz.³⁵

3.2 Membrane Glycolipid Motion

There have been relatively few detailed motional studies of glycolipids in membrane systems. Deuterium lineshape studies of lipids labeled at the C-3 position of the glycerol residue have shown that as the temperature is lowered below the gel–liquid crystalline phase transition, reorientation about the molecular long axis slows. The lineshape changes from one characteristic of axially symmetric motion to one representative of motion having lower than threefold symmetry [Figure 8 (top left)].³⁶ This spectral behavior has been seen in a number of glycolipid systems and has been reproduced in lineshape simulations by a *gauche*(+)*–trans–gauche*(*–*) equilibrium about the C-2–C-3 glycerol bond.

Additional support for such segmental reorientation about the glycerol C-2–C-3 bond has been obtained through ²H T_{1Z} relaxation. Partially-recovered spectra [Figure 8 (left)] of an inversion–recovery experiment for a multilamellar dispersion of the glycolipid β -DTGL labeled at the C-3 glycerol region show complex changes in lineshape as a function

Figure 8 Partially-relaxed ²H spectra of multilamellar dispersions of the β -glucosyl lipid, β -DTGL, labeled at the C-3 position of glycerol at 25°C. Note that the equilibrium spectrum (top left) has a shape consistent with motion having less than threefold symmetry. The intermediate spectra (left) show lineshape changes which reflect anisotropic relaxation. The precise details of the spectral changes depend upon the nature and rate of motion. The spectral changes may be reproduced by theoretical calculations (right) in which a specific motion model is used. In this case the motion was 120° jumps between three unequally populated conformers about the glycerol C-2–C-3 bond. (From Auger et al.³⁶ with permission)

of the relaxation delay.³⁶ Using the motional model that reproduced the low-temperature quadrupolar echo lineshape, the relaxation experiment was simulated and the resulting theoretical lineshape reproduced the experimental spectra very well [Figure 8 (right)].

Another common observation with glycolipids is that at temperatures just below the gel–liquid crystalline phase transition, the ^2H NMR lineshape and intensity (only a few per cent of the original intensity remains) indicate motion is occurring on the 10^{-3} – 10^{-5} s timescale. The nature of the additional motion involved was shown by lineshape simulations to be rotation about the molecular long axis. This was confirmed by two-dimensional chemical exchange experiments.³⁵ When molecular motion is slow ($<10^3 \text{ s}^{-1}$), reorientation of the molecule will cause the ^2H NMR quadrupolar splitting at one particular time to differ a short time later. In simple cases, a change in splitting corresponds to a change in the angle the C– ^2H bond makes with the magnetic field direction—it is possible to measure directly the angle through which a molecule has jumped. If there is no frequency change a diagonal two-dimensional spectrum is observed, whereas frequency changes resulting from the motion lead to off-diagonal peaks or ridges, revealing the frequency correlations. Figure 9 illustrates what happens as β -DTGL is heated from the gel state to the liquid crystalline state. At low temperature the spectrum shows no frequency changes. At 40°C , within the gel state, cross-ridges reveal that molecular motion has occurred during the mixing time. Spectral simulations indicate that the lipid reorients slowly about its long axis, most likely via large angle jumps. It has been suggested that this is a common feature of glycolipid motion in membrane systems.

The elucidation of glycolipid headgroup motion is difficult because of the motional hierarchy: glycolipid headgroup motion would be a combination of the lipid backbone (glycerol or ceramide) motions and rotation about the various glycosidic linkages, the latter representing conformational equilibria. In the case of β -DTGL labeled at the C-1 position of the glucose ring, the experimental $T_{1\rho}$ orientation dependence was well simulated for the average structure and the bilayer orientation shown in Figure 4, and assuming the glycerol isomerization and molecular long-axis reorientation discussed above.³⁷ Quantitative differences between the simulated and experimental spectral lineshapes of relaxation experiments were attributed to the conformational equilibrium about the carbohydrate–glycerol linkage. This equilibrium may involve the range of possible conformations shown in Figure 6 (top).

4 ^1H AND ^{13}C MAGIC ANGLE SPINNING

The methodologies developed for liposomes or oriented micelles require isotopic labeling, a not inconsequential effort. To overcome this difficulty partially and to provide some structural insight into such systems, Oldfield and co-workers have recently used natural abundance ^{13}C and ^1H MAS techniques to study glycolipid–water systems.³⁸ In the liquid crystalline phase the lipids gave well resolved spectra for which resonance assignments could be made. Carbon-13 spin–lattice relaxation times indicated that the glycosyl headgroups and glycerol backbone have similar high-frequency motions. This together with temperature-dependent

Figure 9 ^2H 2D exchange NMR spectra (left) and contour plots (right) of gel state β -DTGL labeled at the glycerol C-3 position. (a) 25°C , $t_{\text{mix}} = 1 \text{ ms}$; (b) 35°C , $t_{\text{mix}} = 0.5 \text{ ms}$; (c) 35°C , $t_{\text{mix}} = 2 \text{ ms}$; (d) 40°C , $t_{\text{mix}} = 2 \text{ ms}$. The cross-ridges seen at 40°C are indicative of reorientation about the molecular long axis. (From Auger et al.³⁵ with permission)

line broadening suggested that the glycerol backbone together with the mono- and disaccharide headgroups behave as a single ‘rigid body’. These findings are in general agreement with results from more detailed ^2H NMR studies. Such an approach offers some promise for investigating a larger range of systems without the need for isotopic labeling.

1 INTRODUCTION

The native environment of most proteins is anisotropic, compromising both crystallographic and solution NMR methods for structure determination. Advantage can be taken of the anisotropy to obtain orientational constraints by solid state NMR.¹⁻⁴ There are inherent advantages and disadvantages associated with these constraints and their use for defining three-dimensional macromolecular structure.

There are two challenges before high quality constraints can be obtained. First, unique spin interactions must be resolved and assigned and, secondly, the samples must be uniformly aligned with respect to a single axis, i.e. three-dimensional or even two-dimensional order is not required, but very high quality one-dimensional order is necessary. For the initial development of orientational constraints as high quality structural constraints specific isotopic labeling of polypeptides has been utilized to achieve resolution and assignments. This is, however, not a fundamental requirement of this structural approach. There have been numerous approaches developed for achieving one-dimensional alignment for many different spectroscopies. NMR has a great advantage in that the experiments are performed in the presence of a strong magnetic field. Provided that the sample is in a liquid crystalline phase the magnetic field can be used to align the bulk phase as in the studies of viruses.^{5,6} In this way it has been possible to achieve uniform alignment of most molecules in a sample relative to a single axis.

The observation of a nuclear spin interaction from such a sample can be used to constrain the orientation of the spin interaction tensor with respect to the magnetic field of the NMR spectrometer. This leads to two conclusions. First, if structural information is to be gained from these data the orientation of the spin interaction tensor with respect to the molecular frame must be known. Secondly, if a structural solution is achieved by this method, then a determination of how the molecule is aligned with respect to the liquid crystalline plane will also be achieved.

Fundamentally, the quality of the structure achieved by orientational constraints is dependent on both the inherent quality of the constraints and on how effectively these constraints can be used. It is difficult to predict analytically the errors in the structure determined by any of the current structural approaches. Similarly, it is difficult for this approach; however, considerable insight into these errors can be gleaned from both the initial and refined structures.

The model system that has been chosen for demonstrating the use of orientational constraints for structure determination is gramicidin A, a 15 amino acid polypeptide that, as a dimer, forms a monovalent cation selective channel across membranes and synthetic lipid bilayers. While it has been known for many years that this peptide forms a channel, and a reasonable model for the folding motif of this polypeptide has existed since 1971,⁷ still there has been no high-resolution structure determination for this peptide in a lipid environment prior to this effort.⁸ However, a solution NMR structure in a detergent environment was achieved in the 1980s and makes for an interesting comparison now that the structure in a lipid environment has been achieved from orientational constraints.⁹

2 OBSERVATION AND QUALITY OF ORIENTATIONAL CONSTRAINTS

A wide variety of orientational constraints can be achieved. In Figure 1 spectra of $^{15}\text{N}_{\epsilon 1}$ Trp9-labeled gramicidin are shown. In Figure 1(a) a single sharp line results from the spin- $\frac{1}{2}$ chemical shift interaction for which the ^{15}N - ^1H dipolar interaction has been decoupled. However, in Figure 1(b) the uniformly aligned sample that gave rise to the spectrum in Figure 1(a) was incubated in a D_2O saturated environment. The resulting spectrum shows the superposition of the chemical shift and the ^{15}N - ^2H dipolar interactions. The 1940 Hz splitting has an error of approximately ± 100 Hz, corresponding to a maximum orientational error of $\pm 1.4^\circ$. Consequently, well aligned samples can be prepared, and observations of both the ^{15}N chemical shift and ^{15}N - ^2H dipolar interactions are shown as orientational constraints. The orientation of the dipolar interaction with respect to the molecular frame is well accepted, in having the unique interaction axis parallel with the internuclear vector. The orientation of the axially asymmetric chemical shift tensor is less certain.

In Figure 2(a) the static magnitudes of ^{15}N chemical shift tensors are shown. These data were obtained on a sample that had been mixed with lipid, hydrated to form bilayers and the channel state of the polypeptide, and then rapidly frozen to generate a static sample without severe distortion due to ice crystal formation.¹⁰⁻¹² The importance of determining the tensor element magnitudes for the site of interest and in the conformation of interest has been elegantly shown by Hiyama et al.,¹³ who reported on work in which a dipeptide crystallized in two different forms and gave rise to very different chemical shift tensors for the same site in the two different crystals. Not only is it important to determine the magnitudes of the tensor elements, but also to determine how the tensor is oriented with respect to the molecular frame. This can be achieved by orienting the chemical shift tensor with respect to an internuclear vector.¹⁴ Here the ^{15}N chemical shift tensor is aligned with respect to the N-C₁ bond axis via the ^{15}N - ^{13}C

Figure 1 Nitrogen-15 chemical shift spectra of $^{15}\text{N}_{\epsilon 1}$ Trp9-labeled gramicidin in uniformly aligned lipid (dimyristoylphosphatidylcholine) bilayers with the bilayer normal parallel to the magnetic field. (a) Sample hydrated with H_2O . The spectrum was recorded at 40 MHz on an Oxford Instruments 400/89 magnet using a Chemagnetics data acquisition system. The radiofrequency electronics were home assembled. All ^{15}N spectra were cross-polarized with high power ^1H decoupling. (b) Sample in (a) that has been opened and exposed to a D_2O atmosphere for 2 days and the loss of moisture replaced with D_2O . The spectrum was recorded at 20 MHz in a narrow bore system, using an IBM/Bruker console with a heavily modified Doty solid state NMR package. Isotopically labeled gramicidin A was synthesized by solid phase peptide synthesis using fluorenylmethoxycarbonyl blocking (Fmoc) chemistry¹⁸

dipolar interaction in a sample that has also been rapidly frozen. The superposition of these two interactions is shown in Figure 2(b).

Not only are the static tensor element magnitudes important, but the spin interaction data need to be interpreted in light of the motionally averaged tensors. Such information can be obtained from the temperature dependence of the chemical shift powder patterns. There are two important features observed from sites in the polypeptide backbone between 200 K and room temperature. First, there is considerable averaging of the tensor elements and, secondly, the asymmetry of the tensor changes with temperature. This latter result means that the librational averaging is anisotropic. In fact, the averaging is consistent with a motional axis described by the axis joining successive α carbons.¹⁵

3 FROM CONSTRAINTS TO MOLECULAR STRUCTURE

An initial structure of the gramicidin backbone can be assembled from N–H and N– C_1 dipolar constraints for

Figure 2 Nitrogen-15 chemical shift powder pattern spectra of ^{15}N Val8-labeled gramicidin. Samples in hydrated lipid bilayers were rapidly cooled by plunging thin films into liquid propane. The sample was then stored at liquid nitrogen temperatures before transfer to the precooled NMR probe.¹⁵ (a) The single-site isotopically labeled preparation providing the static chemical shift tensor for the site of interest in the conformation and environment of interest. (b) Spectrum of gramicidin that is also $^{13}\text{C}_1$ Val7-labeled. The powder pattern also displays the ^{15}N – ^{13}C dipolar interaction. From the spectral analysis the relative orientation of the dipolar and chemical shift interactions can be achieved

each peptide plane. However, each constraint has ambiguities associated with its interpretation. For each constraint the spin interaction frequency is related to an angle through a $\cos^2 \theta$ term and, therefore, the sign of $\cos \theta$ is undetermined. Furthermore, the sign of the dipolar coupling is also unknown except for those cases where the splitting is greater than half-maximal. These ambiguities would accumulate to a plethora of structural possibilities except that most combinations are not consistent with the known bond angles of the polypeptide backbone. Other combinations are not consistent with the observed ^{15}N chemical shift. For an initial structure the peptide planes are assumed to be planar (i.e. the ω torsion angle is assumed to be 180°). By taking advantage of the tetrahedral geometry and the orientation of adjacent planes relative to a common axis it is possible to achieve the relative orientation of the peptide planes (i.e. the ϕ , ψ torsion angles). Such a structural unit, known as a diplane unit, can then be combined with the adjacent diplane which shares a common plane. Only those common planes having an identical orientation can be combined. The result for gramicidin is two closely related conformers (1 and 2 in Figure 3). Interestingly, as the structure

Figure 3 Two initial structures have been achieved from orientational constraints. Only half of the symmetric dimeric channel structure is shown. Both structures have the same folding motif: 6–7 residues per turn, a β -sheet type structure, and a right-handed helix. However, significant structural differences exist

was assembled from the original combination of two diplanes the structural ambiguities did not increase, but remained as just two possibilities. This is because the data for each additional peptide plane is unique and independent of the data used previously. Furthermore, the constraints are all relative to a single common axis, the magnetic field direction and channel axis of the polypeptide dimer.

Both of the initial structures have the same folding motif: 6–7 residues per turn, a β -sheet type of hydrogen-bonding pattern and a right-handed helical sense. Both structures also have an uninterrupted pattern of alternating peptide plane orientations. This is clearly seen in Figure 4, where each peptide plane is shown edge on with the vertical axis being the channel axis with the channel center to the left of each frame. For both structures the peptide planes alternate between being approximately parallel to the channel axis (the even–odd planes) and being tipped by approximately 20° with respect to the channel axis (the odd–even planes). The fundamental difference between these two structures is that conformer 1 has the carbonyl oxygens oriented in toward the channel center for those planes having a significant tilt and conformer 2 has these planes oriented with the carbonyl oxygen away from the channel center. Considering that this channel is a cation selective channel it is unrealistic to think that carbonyl oxygens would be preferentially turned away from the channel axis. Consequently, conformer 1 is the favored possibility.

4 FROM INITIAL TO REFINED STRUCTURE

For these initial structures not all of the orientational constraints have been optimally utilized. Nitrogen-15 and ^{13}C chemical shifts, ^2H quadrupolar interactions, and, now that the hydrogen-bonding pattern has been identified, ideal N–O and H–O distances can be used as structural constraints. A refinement protocol has been developed in which slight changes to the torsion angles, including the ω torsion angle which had been fixed at 180° , are made followed by a calculation of the observables. The difference between calculated and experimental values generates a penalty function which is minimized through numerous cycles of torsion angle modifications in this simulated annealing approach to refinement. Although the torsion angles for the refined structures are typically very close to the initial structure, there are significant differences. The refinement has also adjusted the residues per turn of the helix and the pitch as seen in Figure 5.

5 STRUCTURAL QUALITY

The inherent quality of these orientational constraints has been clearly demonstrated through the achieved structure. The errors associated with each observed constraint can be reasonably estimated. Accumulated structural errors can be estimated from the comparison of initial and refined structures. These latter errors were small enough so that the complete hydrogen-bonding pattern was defined by the initial structure. And yet it is clear that significant improvements or minimization of the errors can be achieved through experimental procedures designed to minimize conformational heterogeneity. Also, more accurate characterization of the local dynamics will improve the accuracy of the structural analysis. Not only can the structure be improved with better constraints but the quantity of the constraints can be used to great advantage through a refinement protocol. The primary advantage that the orientational constraints have over other structural constraints is that each constraint is absolute, i.e. it is relative to the fixed laboratory frame of reference. Unlike solution NMR and solid state NMR distance constraints which

Figure 4 A view of each peptide plane in the two initial gramicidin structures displayed in Figure 3, as viewed along an axis defined as perpendicular to the channel axis in the peptide plane. The channel axis is vertical, and the circles represent the carbonyl oxygen atom. The inside of the channel is displayed on the left side of each frame. Each pair of orientations is symmetric because of the symmetry of the orientational constraints. There is an alternating pattern for the orientation of the carbonyl groups between large and small angles to the channel axis. The structure (1) with open circles that has the carbonyl oxygens tipped furthest into the channel and least to the membrane environment is considered the likely structural conformer. ALHD represents the formyl blocking group of the amino terminus and ETAM represents the ethanolamine

Figure 5 The refinement process against all of the experimental data and ideal hydrogen-bonding distances yields a very consistent set of structures that differs significantly from the initial structure shown as the fine line. Only the backbone atoms of C_α , N, and C_1 are displayed for the monomer in this figure, since the dimer is symmetric

relate the position of one site relative to another in the molecule, here the orientation of one site in the molecule is related to a fixed frame of reference that is the same for each constraint.

There have been few occasions when a structure of a polypeptide or protein has been determined in a lipid environment. Here the lipid bilayer generates an environment that strengthens electrostatic interactions, thereby minimizing large amplitude motions induced by hydrogen bond exchange. Through a high resolution structure and dynamics characterization details of how cation passage through this channel is facilitated by this polypeptide will be elucidated. Not only are the carbonyl oxygens oriented in toward the channel axis, but local motions of the backbone occur on the nanosecond timescale.¹⁶ Such overdamped motions could result from correlated motions or coherence that propagates through the channel and bilayer at a rate coincident with the kinetic rate for cation translocation. In fact, the 10 ns timescale that has been determined for the molecular motions is also the kinetically estimated rate for the cation to move from one carbonyl binding group to another. Furthermore, the motions of the single file of water molecules must be correlated since the cations cannot pass around these molecules in the channel. Therefore, if the water molecules have correlated motions then the motions of the carbonyl groups that surround this column of water molecules must also be correlated.

Such structure–dynamics–function correlations can be achieved with the high-resolution characterization possible from solid state NMR and orientational constraints. While isotopic labeling and solid phase synthesis have been used to generate resolution and assignments, approaches with ^1H and ^{14}N NMR¹⁷ have been described which could yield numerous constraints in a single spectrum without isotopic labeling or with uniform ^{15}N labeling. Although the complete structure determination of sizeable proteins may remain a monumental task for this approach the determination of a domain or

structural subunit to high resolution is feasible, as is the high-resolution structure of a ligand bound to a uniformly aligned receptor.

1 INTRODUCTION

Lipids are a structurally diverse class of biological molecules that are defined on the basis of their solubility in organic solvents. Lipids are involved in numerous metabolic processes including energy metabolism and hormone biosynthesis. They are also important structural components of biological membranes. Biological membranes are fluid, noncovalent assemblies of lipid and protein which form the external boundary and internal compartments of eukaryotic cells, thereby allowing local environments appropriate to particular functions. Membranes are also selective permeability barriers which provide a means of regulating cellular concentrations of ions and metabolites. The essential structural features of membranes are described by the fluid mosaic model, which was proposed by Singer and Nicholson over 20 years ago.¹ In this model, the lipid components are arranged in lamellar sheets with a thickness of two molecules (about 4 nm), providing a fluid matrix into which proteins can insert or associate at the surface. The lipid bilayers form spontaneously in water, as a result of the amphipathic nature of the lipid molecules.

Membranes contain a remarkable diversity of lipids which exceed the requirements for basic structural functions. For example, although a single lipid such as phosphatidylcholine can form fluid semipermeable bilayers, biological membranes typically contain over 100 lipid components. That the synthesis and transport of these lipids requires significant metabolic expenditure suggests specific biochemical or physicochemical roles for the individual components of membranes. Efforts to clarify these roles have been a focus of membrane biology for over three decades, with the task still ongoing. Much insight has been gained through investigations of the physicochemical properties of model systems formed from different membrane lipids. The pioneering X-ray diffraction studies of Luzzati et al. revealed that isolated membrane lipids could, upon hydration, adopt fluid phases (known as mesophases) other than the bilayer, a phenomenon referred to as lipid polymorphism.² While elucidation of the structure of many of these mesophases was accomplished using X-ray diffraction, a great deal of information pertaining to the phase behavior and physical properties of different lipid mesophases, for both pure and mixed lipid assemblies, has come from solid state ³¹P and ²H NMR.^{3–7} This review will discuss the information provided by magnetic resonance techniques, and attempt to place these data within a biological framework. The importance of lipid

polymorphism stems not only from the interesting biophysics of lipid–water assemblies, but from the insight which it provides into many aspects of membrane function.

2 LIPID POLYMORPHISM AND NMR

2.1 Lipid Structure and Diversity

The main classes of lipids found in eukaryotic membranes include the glycerophospholipids, the sphingolipids, and cholesterol.⁸ Lipids found in the former group include phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI), and cardiolipin (CL). The type of phospholipid is determined by the polar headgroup, which is attached to position 3 of the glycerol backbone; fatty acyl chains occupy the other two positions. The structures of a representative PC and PE are shown in Figure 1 (see legend for details). The two lipids differ only at the headgroup nitrogen, which is protonated in PE and trimethylated in PC. The sphingolipids are derivatives of the long-chain base sphingosine. The headgroup can be the same as that of PC (giving sphingomyelin), or a hydroxyl group (giving ceramide), or can contain a variety of sugars (giving the glycosphingolipids). A single fatty acyl chain attaches to sphingosine via an amide bond. Cholesterol is a sterol; a hydroxyl group is found at one end of its rigid ring system and a branched hydrocarbon chain at the other.

This brief summary of the main lipid groups illustrates the heterogeneous nature of biological membranes. This is

Figure 1 Chemical structures of representative phospholipids: (a) 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) and (b) 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine (POPE). The stereospecific numbering of the glycerol backbone is shown in (a). POPC has a cylindrical shape which favors the bilayer phase, whereas POPE has a cone shape which favors the H_{II} phase

further compounded by variation in fatty acid chain length and degree of unsaturation, as well as the presence of minor lipid components.

2.2 Lipid Polymorphic Phases

Lipids pack within a bilayer such that the headgroups form the aqueous interface of the membrane surface, while the fatty acyl chains form the hydrophobic membrane interior [Figure 2(a)].¹ Lipid bilayer models include multilamellar vesicles (MLVs), oriented multibilayers, and large and small unilamellar vesicles (LUVs and SUVs, respectively).⁹ For NMR studies of polymorphism, MLVs have been utilized almost exclusively. These large quasispherical structures (1–10 μm diameter) are easily formed by dispersing lipid in water with vortexing and (often) several cycles of freezing and thawing. In addition, they are large enough so that tumbling of the MLV, or lateral diffusion of lipids around the MLV do not result in significant motional averaging effects. As a result, broadline ^{31}P and ^2H spectra are observed.

Some membrane lipids, PE in particular, adopt the hexagonal H_{II} phase in isolation [Figure 2(b)].^{3,10} This nonbilayer phase is composed of hexagonally packed lipid cylinders, where the phospholipid headgroup points towards the center of the cylinder, forming an aqueous channel with a diameter of approximately 2 nm. Most lipids that adopt the H_{II} phase can also adopt the bilayer phase if the temperature is low enough; transitions between the two phases are rapid and reversible, although little exchange of lipid between these phases appears to occur when they coexist.¹¹

Other nonbilayer phases include micellar structures and cubic phases, in which the lipid aggregate forms a three-dimensional lattice.¹² The structures of the cubic phases are quite complex, and will not be described here. In general, neither the H_{II} nor cubic phases are observed as long-lived structures in vivo. The reason these phases are of interest in a biological context stems from evidence suggesting that

some of the intermediates of bilayer to nonbilayer transitions are involved in processes such as membrane fusion (see Section 3).^{3,13,14}

2.3 Phosphorus-31 NMR

Phosphorus-31 NMR has been widely used in the study of membrane structure and lipid polymorphism.^{3,4} Phosphorus-31 is a spin- $\frac{1}{2}$ nucleus with a natural abundance of 100%, found in membranes only in the headgroups of phospholipids and sphingolipids. All of the common phospholipids give rise to broad ^{31}P NMR spectra, where the spectral width can range from 20 to 200 ppm depending on the mesophase being examined and the extent of hydration. Because ^{31}P NMR spectra are almost always acquired with broadband decoupling (to remove ^1H - ^{31}P dipolar interactions), the observed lineshape depends on the types of motions which average the shielding anisotropy of the phosphate group. The nonaxially symmetric shielding tensor gives rise to three principal components, which are observed in spectra of anhydrous lipid, having widths of the order of 200 ppm.⁴ In liquid crystalline MLVs, rapid axial rotation averages the components of the shielding tensor in the plane of the membrane, giving rise to the classic 'powder pattern' lineshape [Figure 3(a)] with a width of 40–50 ppm.³ The origin of this lineshape is discussed by Cullis and DeKruijff and by Seelig.^{4,15}

In the H_{II} phase, rapid diffusion of lipid about the cylinder long axis provides an additional mechanism of motional averaging.^{3,4,10,15} The result is a powder pattern which, compared with that of the bilayer, is reduced by a factor of two and has the opposite sign [Figure 3(b)]. This allows transitions between the two phases to be conveniently and accurately monitored. The correlation between phase determinations by

Figure 2 Schematic cross-sectional representation of (a) the liquid crystalline bilayer and (b) hexagonal H_{II} phases, showing how these phases favor the packing of cylindrical and cone shaped lipids, respectively. The H_{II} cylinder axis is normal to the plane of the paper

Figure 3 Phosphorus-31 NMR spectra of different liquid crystalline polymorphic phases: (a) multilamellar dispersions of dimyristoyl-PC (DMPC) at 30 °C (b) hexagonal phase dioleoyl-PE:cholesterol (1:1) at 20 °C (c) LUVs of dioleoyl-PC containing 20 mol% phosphatidic acid at 20 °C

^{31}P NMR and small-angle X-ray diffraction has been shown to be excellent.¹⁶

The cubic phases, although structurally diverse, allow the phospholipid molecules to sample all angles in a period short on the NMR timescale, i.e. they allow isotropic averaging of the powder lineshape.^{3,12} This results in a narrow peak at the isotropic chemical shift, which is difficult to differentiate from that produced by micelles, SUVs, or some LUVs [Figure 3(c)]. Lipid mixtures containing nonbilayer lipids often exhibit isotropic peaks,¹² which are said to originate from 'isotropic phase' lipid.

Phosphorus-31 NMR is clearly a convenient tool for monitoring the polymorphic phase preferences of pure and mixed lipid assemblies. Although techniques such as X-ray diffraction and freeze-fracture electron microscopy have arguably been of equal importance,^{2,17} the advantages of NMR, primarily in convenience and rapidity, have made it the technique of choice for characterizing a variety of different lipids and their response to variation in parameters such as pH, temperature, and ion concentrations. These results are summarized in the next section.

2.4 Lipid Polymorphic Phase Preferences

A comprehensive tabulation of the polymorphic phase preferences of a large variety of pure and mixed lipid systems is given in Cullis et al.¹⁸ A number of interesting observations have emerged from these data. In single-component systems, a few lipids favor the bilayer phase almost exclusively: these include the PCs, PI, sphingomyelin, diglucosyldiglyceride (DGLcDG), and digalactosyldiglyceride (DGalDG). Other lipids can adopt either the lamellar or H_{II} phase depending on the conditions; these include PE, PS, phosphatidic (PA), phosphatidylglycerol (PG), and CL. Two of the glycolipids [monoglucosyldiglyceride (MGLcDG) and monogalactosyldiglyceride (MGalDG)] adopt the H_{II} phase exclusively.

Of the nonbilayer phase lipids, PE has been most extensively studied.^{3,10,14,18} PEs form stable bilayers at sufficiently low temperatures, undergoing a transition to the H_{II} phase as the temperature is raised above some critical value. Increasing the level of acyl chain unsaturation favors the formation of the H_{II} phase. Other lipids, such as PS and phosphatidic acid, will only form the H_{II} phase below pH 3.5, where the negative charge on the headgroup is neutralized. Similarly, phosphatidic acid and CL will adopt the H_{II} phase in the presence of Ca^{2+} , which neutralizes the negative surface charge. These observations have biological relevance, as they indicate possible mechanisms (control of pH and divalent ion concentration) available to the cell to regulate bilayer–nonbilayer transitions in an isothermal environment.

Phosphorus-31 NMR has also proven useful in characterizing the polymorphism of multicomponent systems, which bear a greater resemblance to biological membranes than pure lipid systems. This has resulted in two important observations. Firstly, mixtures of bilayer and nonbilayer lipids will progressively favor the bilayer phase as the proportion of bilayer-forming lipids is increased; sometimes as little as 20 mol% of the bilayer lipid will completely stabilize the lamellar phase.^{3,14} Secondly, cholesterol may play a role in regulating bilayer to nonbilayer transitions in complex systems. Cholesterol can

induce the formation of H_{II} phase in PE-containing bilayer systems that have been stabilized by PC.¹⁴

The substantial body of data on lipid polymorphic behavior has led to theoretical insight into the factors which determine the phase preference of a given lipid system. One of the most successful approaches, developed by Israelachvili et al.,¹⁹ involves consideration of the molecular shapes of individual lipid molecules. The basic idea is that molecules with different shapes will preferentially pack in phases of different symmetry. As illustrated in Figure 1, lipids such as PC which favor the lamellar phase have similar average cross-sectional areas in the headgroup and acyl chain regions, and are thus said to be 'cylindrical'. Lipids such as PE have a cone shape, where the headgroup occupies a smaller cross-sectional area than the acyl chains, thereby imparting a curvature to the assembly that favors the H_{II} phase (see Figure 2). For detergent-like lipids which form micellar structures the geometry is reversed, giving an inverted cone where the headgroup cross-sectional area is greater than that of the chains. To see how this can provide insight into polymorphic phase transitions, consider the lamellar to hexagonal transition of dioleoyl-PE (DOPE). At temperatures less than 10 °C the lipid chains are sufficiently ordered to impart a cylindrical molecular geometry [see Figure 1(a)] that favors the bilayer phase [see Figure 2(a)]. Elevating the temperature increases the extent of acyl chain molecular motion, resulting in a greater cross-sectional area of the hydrocarbon chains relative to the headgroup. This results in a cone geometry [see Figure 1(b)] that favors the H_{II} phase at room temperature [see Figure 2(b)]. Similar considerations explain why neutralizing the charge of the headgroup, either via pH or divalent cations, leads to the formation of the H_{II} phase in other lipids. Charged headgroups repel and are therefore larger; neutralizing the charge reduces their effective size thereby imparting cone geometry to the lipid.

A more quantitative approach to understanding the factors involved in the formation of nonbilayer phases has come from the 'curvature' concept introduced by Gruner.²⁰ In this model, the lamellar to hexagonal transition is described as a tendency for nonbilayer lipids to force a monolayer to curl into cylinders with a spontaneous radius of curvature R_0 ; the magnitude of this parameter, which can be measured by X-ray diffraction, provides a measure of the polymorphic tendencies of a lipid system. A lipid with a strong tendency to form the H_{II} phase will have a small radius of curvature, whereas a system with less tendency, such as a PC/PE mixture, will have a larger radius of curvature. Studies on DOPE and its methylated derivatives reveal that while systems with small and large R_0 form hexagonal and lamellar phases, respectively, those with intermediate values have a strong tendency to form cubic phases.²¹

2.5 Deuterium NMR

Deuterium NMR is a powerful technique for the study of molecular order and dynamics in model and biological membranes.^{5–7} The theory and application of ^2H NMR have been extensively reviewed; we will summarize only those aspects relevant to the study of polymorphism. Deuterium is a quadrupolar nucleus ($I = 1$) whose behavior is dominated by the quadrupolar interaction, and is therefore sensitive primarily to intramolecular motions of the C– ^2H bond. In anisotropic

dispersions such as MLVs, each C–²H bond gives rise to a ‘powder pattern’ lineshape, also known as a ‘Pake doublet’. The separation between the two maxima is the quadrupolar splitting $\Delta\nu_Q$, which, for deuterons on the acyl chain carbons, is related to the carbon–deuterium bond order parameter S_{CD} by

$$\Delta\nu_Q = \frac{3}{4}\chi S_{CD} \quad (1)$$

where χ is the quadrupolar coupling constant. The order parameter provides a measure of the angular excursions of the acyl chains about the surface normal. For lipids containing several deuterons, a superposition of Pake doublets is obtained [Figure 4(a)]. This is problematic for measurements of S_{CD} only if the splittings cannot be assigned.

Deuterium NMR can be used to assess lipid polymorphic preferences, and in this way provides analogous information to ³¹P NMR. In addition, the use of selectively deuterated lipids allows monitoring of the phase behavior of individual components of mixed phospholipid systems, as exemplified by the Ca²⁺ triggered lamellar to H_{II} transition for [²H]dioleoyl-PS ([²H]DOPS) in DOPE/dioleoyl-PC/[²H]DOPS/cholesterol (1:1:1:3).²²

A fascinating polymorphic system recently investigated by ²H NMR models the intercellular lipid lamellae of mammalian stratum corneum, the uppermost layer of skin.²³ The model, composed of ceramide, cholesterol, and perdeuterated palmitic acid (1:1:1), displays a complex polymorphism, with the palmitic acid partitioning into solid, gel, liquid ordered, hexagonal, and isotropic phases depending on the temperature and pH.²³ The ²H NMR spectrum obtained at 50 °C and pH 5.2, where the palmitic acid is neutral, reveals liquid ordered membranes (plateau $S_{CD} = 0.4$), which are significantly more ordered than liquid crystalline bilayers but have the same lineshape [Figure 4(a)]. Heating to 75 °C induces an isotropic phase [Figure 4(c)]. However, if the pH is adjusted to 7.4,

Figure 4 Deuterium NMR as a technique for assessing lipid polymorphic preferences. All of the spectra are equimolar dispersions of ceramide:cholesterol:palmitic acid-*d*₃₁, which approximates the composition of mammalian stratum corneum. (a) Liquid ordered membranes (maximum $S_{CD} = 0.4$) acquired at pH 5.2 and 50 °C. (b) Hexagonal H_{II} phase at 75 °C, acquired after adjustment of the pH to 7.4. (c) Isotropic phase at 75 °C and pH 5.2. (We thank Dr Jennifer L. Thewalt and Dr Neil Kitson for providing the spectra)

where the palmitic acid is negatively charged, the same temperature increase triggers a transition to the H_{II} phase [Figure 4(b)]. In this case the charge on the palmitic acid (i.e. size of the headgroup) regulates the phase induced at elevated temperatures. Furthermore, if the system is prepared with sphingomyelin instead of ceramide (where the former contains a phosphocholine headgroup compared with the hydroxyl group of the latter), then at low pH the membranes are liquid ordered over a wide temperature range and no polymorphism is observed.²³

In addition to phase preferences, ²H NMR can provide information concerning variation in orientational order in the hydrocarbon region of lamellar and hexagonal phases. For lipids containing a perdeuterated acyl chain, dePaking and integration methodology allows the complete order profile to be derived from a single spectrum.²⁴ This has been applied to dispersions of 1-[²H₃₁]palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC-*d*₃₁) and POPE-*d*₃₁, and mixtures thereof.^{25–27} Significant differences are observed in the lamellar and H_{II} phases (Figure 5). The variation of S_{CD} in bilayers shows little change from carbons 2 to 10 (the plateau region), followed by a rapid drop in order toward the center of the bilayer. In the inverted hexagonal phase, the magnitude of the order parameters is decreased by at least a factor of two, and the plateau region is essentially nonexistent, giving a relatively linear decrease in order down the length of the chain. This results from looser packing of carbons 2 through 8 in the H_{II} phase.^{25,26} The results indicate that order parameters are sensitive to the lipid phase symmetry, suggesting a relationship between the order profile and lipid polymorphic tendencies. This is further supported by the ability of nonbilayer lipids to modulate the order profile of a lamellar matrix. The introduction of POPE into POPC (or DOPE into DOPC) increases the order of the bilayer lipid.^{25,27,28} Whether the changes in order parameters are as predictive of polymorphic preferences as changes in parameters such as R_0 remains to be seen.

Figure 5 Smoothed order parameter profile of bilayer phase POPC-*d*₃₁ (■) and hexagonal phase POPE-*d*₃₁ (□), obtained by integration of dePaked spectra acquired at 30 and 70 °C, respectively. The two profiles are normalized, but the absolute order parameters of the H_{II} phase at C-2 are approximately half those of the bilayer phase. (We thank Dr M. A. Monck for providing the data)

3 BIOLOGICAL IMPLICATIONS OF LIPID POLYMORPHISM

Although nonbilayer lipids are constrained to the lamellar phase in biological membranes, the study of lipid polymorphism has provided insight into several aspects of membrane function. Nonbilayer lipids may be involved in the regulation of certain membrane enzymes, and in some cases this regulation may involve modulation of membrane order, which can be achieved by controlling the ratio of bilayer to nonbilayer lipids. One example comes from ^2H NMR studies on the microorganism *Acholeplasma laidlawii* strain B, where perdeuterated palmitic acid was biosynthetically incorporated into the cell membrane. Growth of the microorganism could only occur over a fairly narrow range of order ($0.14 < S_{\text{CD}} < 0.18$).²⁹ Maintenance of the order profile was attributed to the ratio of MGlcDG to DGlcDG, which in isolation prefer the H_{II} and bilayer phases, respectively. The failure of the organism to thrive outside this range of order suggests an order requirement for optimum membrane protein function.

Nonbilayer lipids may play an important role in membrane fusion. LUVs made of charged and nonbilayer lipids (such as PE and PS) can often be induced to fuse in the presence of Ca^{2+} to form larger lamellar structures which then rearrange to the H_{II} phase.¹⁴ When these same systems are studied as MLVs, they undergo lamellar to H_{II} transitions. Certain lipid soluble fusogens, such as monoolein, are capable of inducing H_{II} or cubic phase structure in model and biological membranes.^{12,14} Clearly, membrane fusion cannot occur without local, transient departures from bilayer morphology at the fusion interface. These observations provide strong evidence that fusion proceeds via nonbilayer intermediates.¹³

Our understanding of the link between lipid polymorphism and membrane fusion owes much to the work of Siegel,¹³ who has developed a unified description of both lamellar to hexagonal and lamellar to cubic transitions. Siegel has proposed that the first fusion intermediates are either inverted micellar intermediates (IMIs) or stalk structures, which form between apposed bilayers at appropriate temperatures, and then assemble into either H_{II} phase or cubic phase precursors [the latter are also referred to as interlamellar attachments (ILAs)]. The particular path chosen is a function of the spontaneous radius of curvature of the membrane,³⁰ but only the latter path (ILAs) leads to membrane fusion. The highly curved ILA structure explains the narrow 'isotropic' resonances often observed in lipid mixtures by ^{31}P NMR. Liposome fusion has been observed to occur only over the same narrow temperature range where isotropic ^{31}P NMR resonances are observed.³⁰

1 INTRODUCTION

Membrane proteins are responsible for many important biological functions, including some that are unique, such as those of receptors and ion channels, as well as some that overlap with those of soluble proteins, such as enzymes. Even though more than half of all proteins are associated with membranes, and there are many additional reasons to be interested in their structural biology, only a few high-resolution structural studies of membrane proteins have been reported.^{1–4} This is largely because samples of membrane proteins are problematic for the most commonly used methods of structural biology. Proteins complexed with lipids are difficult to crystallize in forms suitable for X-ray diffraction and conventional multidimensional solution NMR methods are hampered by their slow overall reorientation rates. However, in spite of its limitations, NMR spectroscopy has played an important role in the characterization of membrane proteins and, more importantly, it has the potential to play a dominant role in future studies. The development of high-resolution solid state NMR methods gives NMR spectroscopy sufficient versatility to determine the structures and describe the dynamics of proteins in bilayer samples. Further development of the instrumentation and methods for multidimensional solution NMR spectroscopy will also improve its effectiveness in studies of membrane proteins in micelle samples.

The key to NMR studies of membrane proteins is sample preparation.⁵ Figure 1 illustrates the molecular arrangements in phospholipid bilayers and detergent micelles, the two well-characterized model membrane systems used in a wide variety of biophysical investigations including NMR spectroscopy. Each micelle, of detergents most commonly used in NMR studies, contains approximately 50–60 single chain lipid molecules and a single polypeptide. In contrast, lipid bilayers are very large supramolecular structures with many phospholipid and polypeptide molecules in extended two-dimensional arrays. Proteins in micelles reorient relatively slowly, although rapidly enough to be suitable for most heteronuclear multidimensional solution NMR experiments in high-field spectrometers, while those in bilayers are immobile on the relevant

Figure 1 Schematic drawings of a protein in membrane environments: (a) detergent micelle; (b) phospholipid bilayer

NMR timescales, enabling them to be treated spectroscopically as solids. Therefore, the most important advantage of utilizing these two different types of model membrane is that they permit the use of both high-resolution solid state NMR and multidimensional solution NMR methods with membrane proteins. The results from these two essentially independent spectroscopic approaches can be combined to describe structural features of membrane proteins that are otherwise inaccessible to any single method of structure determination. Solid state NMR spectroscopy of oriented and unoriented bilayer samples and multidimensional solution NMR spectroscopy of micelle samples are most effective when the proteins are suitably labeled with stable isotopes and the samples are carefully prepared. The dynamics of backbone and side-chain sites can be described over a wide range of timescales through the analysis of nuclear spin relaxation in both micelle and bilayer samples, and motionally averaged powder pattern lineshapes in bilayer samples.⁶ Local protein motions have a dramatic effect on many spectral parameters; therefore mobile residues in loop and terminal segments can be readily identified in both types of sample.^{7,8}

2 EARLY NMR STUDIES OF MEMBRANES

NMR spectroscopy was applied to proteins within a decade of its initial demonstration. The first NMR spectrum of a protein reported in 1957 was that of a small globular protein, ribonuclease, in aqueous solution.⁹ This spectrum, despite its low sensitivity and limited resolution, encouraged additional development by demonstrating the basic feasibility of NMR spectroscopy for the study of proteins in aqueous solution. However, the development and application of NMR spectroscopy has been conspicuously focused on soluble proteins that do not aggregate and reorient rapidly in solution. Technical advances, especially high-field magnets and small, fast computers, and methodological advances, especially multidimensional experiments utilizing pulsed irradiation at several rf frequencies, led to the development and implementation of approaches to structure determination of globular proteins in solution by the mid-1980s.^{10,11}

The immediate application of NMR to the study of membrane proteins was precluded by the difficulty of identifying resonances that could be attributed to the relatively small amounts of protein in spectra dominated by resonances from the highly abundant lipids and by the broad lines and hence, poor sensitivity and resolution obtained from proteins bound to native membranes, or multilamellar liposomes or sonicated vesicles in reconstituted systems. For these reasons the majority of the early NMR studies of membrane systems was

devoted to dynamics and organization of the lipids in bilayers, and to some extent the influence of proteins and peptides on the properties of the lipids. Nevertheless, the results of NMR experiments, especially in combination with those from contemporary ESR experiments, strongly influenced the understanding of biological membranes as dynamic entities. The NMR studies gave a picture of protein–lipid interaction where the proteins generally have a disordering effect on the membrane lipids; there is little evidence of selectivity in the interaction between proteins and lipids, with the exception of some charged species; and there is a fast exchange between protein-associated and bulk lipid, on the NMR timescale. There are a number of thorough review articles on these subjects.^{12,13}

A substantial amount of the early research on membranes was devoted to conformational studies of small membrane active polypeptide antibiotics and their interactions with phospholipids. Certain such peptides are known to induce cation permeation across cells and artificial membranes, and to form lipid soluble complexes. Early NMR studies of peptides such as alamethicin and gramicidin^{14,15} set the stage for later detailed investigations of peptide ion channels and their interaction with membranes.

The initial studies of native and reconstituted membranes demonstrated that high-resolution NMR spectra suitable for detailed structural analysis of membrane proteins could not be readily obtained.¹⁶ Sonicated vesicle samples have the advantage of being bilayers, albeit highly curved, and sealed chambers suitable for transport studies. Although spectra obtained from lipids in sonicated vesicles are considerably narrower than those in multilamellar bilayers, the overall correlation time (approximately 10^{-6} s) of the vesicles is extremely inconvenient. This means that any resonances from protein, or other molecular constituents immobilized within the vesicle are very broad because of efficient relaxation.¹⁷ These resonances do not respond to solid state NMR procedures because their breadth is due to relaxation rather than powder pattern characteristics. Therefore there have been very few ^1H or ^{13}C NMR studies of proteins in vesicles. However, some results have been obtained with ^{19}F -labeled proteins, since the number of resonances is greatly reduced and there is no interference from lipid resonances. For example, the motional properties of the M13 major coat protein, fluorinated at its two tyrosyl residues, have been examined in this manner.^{18,19} The filamentous bacteriophage coat proteins have turned out to be very valuable model systems for many types of NMR study of membrane proteins.

In 1968, Kamat and Chapman²⁰ showed that the resolution and sensitivity of ^1H NMR spectra could be substantially improved by solubilizing native membranes in lysolipid or detergent micelles. Around 1979, the first high-resolution NMR studies of membrane associated peptides in small perdeuterated micelles were reported.^{21,22} The relatively well-resolved spectra, and the observation of homonuclear NOEs in well-behaved and stable samples set the stage for many fruitful multidimensional solution NMR studies of membrane associated peptides and proteins.

3 APPLICATIONS TO MEMBRANE PROTEINS IN MICELLES

Multidimensional solution NMR methods can be applied to peptides and proteins in micelles because the reorientation

of the protein–micelle complex in solution is rapid enough to average the spectral parameters from the various nuclear spin interactions to their isotropic values. This enables the indirect effects of their fluctuations, as monitored by relaxation phenomena, to describe local dynamics as well as provide spatial information in the form of relative proximities. However, the methods of solution NMR spectroscopy are somewhat limited, at least compared with what can be done with well-behaved globular proteins in solution, by the broad linewidths and efficient spin diffusion that accompany the relatively slow reorientation of protein–micelle complexes in solution. These limitations can be minimized with careful sample preparation, especially through specific, selective, and uniform isotopic labeling of the protein, and through careful preparation of the micelles by ensuring sufficient detergent and salt concentrations to form uniform, small micelles.²³ Some membrane proteins are soluble in organic solvents or mixed aqueous solvents without lipids, and these preparations have been used in NMR studies. While well-resolved protein resonances can be observed in many cases, there is always considerable concern about the status of the protein in these solvents, especially in the popular trifluoroethanol because of its helix forming propensity. However, as the methods for studying proteins in micelles improve, there is less need to rely on solubilizing membrane proteins in organic solvents.

Protein structure determination by multidimensional NMR spectroscopy is straightforward for relatively small globular proteins in solution, especially when uniformly ^{15}N and ^{13}C labeled samples are available. There are several basic steps in protein structure determination, as widely utilized with globular proteins in aqueous solution, including: the resolution and assignment of backbone and side-chain resonances based on through-bond and through-space interactions observed in multidimensional NMR spectra; the measurement of many homonuclear ^1H – ^1H NOEs among the assigned resonances, supplementing these short range distances with other structural constraints including spin–spin coupling constants; the interpretation of all structural constraints in terms of secondary structure; and the generation of a family of three-dimensional protein structures using distance geometry, molecular dynamics, and other calculations.

Melittin has been studied extensively by NMR spectroscopy after its initial use as an example to show the feasibility of micelle samples.^{24,25} This 26-residue peptide disrupts membranes. Solution NMR studies of melittin in detergent micelles show that the amino terminal and carboxyl terminal regions are α -helical and separated by a kink. The NMR data from melittin have been subjected to considerable refinement, and provide a model for other amphipathic helical peptides that interact with membranes. The bombolittins are another class of peptides isolated from the venom of bees, whose functions include the lysis of erythrocytes and liposomes. The structures of bombolittin I and III have been investigated by ^1H NMR both in sodium dodecyl sulfate (SDS) micelles and in aqueous solution.²⁶ In micelles the presence of strong $\text{NH}(i)$ – $\text{NH}(i+1)$ NOEs over the full range of the molecules is indicative of helical structures. In water, bombolittin I lacks any observable secondary structure, while bombolittin III adopts a highly helical structure which is believed to arise from extensive peptide aggregation.

Membrane modifying channel-forming peptides of fungal origin, that are rich in hydrophobic amino acids including α -aminoisobutyric acid (Aib), have been the focus of many NMR investigations. Alamethicin is a 20 amino acid peptide known to induce voltage gated conductance in bilayers. This peptide has been studied extensively by solution NMR, both in organic solvents and, more definitively, in SDS micelles.²⁷ Interproton distances obtained from the NOE data suggest a structure for alamethicin where the amino terminus is predominantly α -helical while the carboxyl terminus is less regular and more flexible.

δ -Hemolysin is another 26 residue peptide that interacts with membranes. NMR studies of the peptide in micelles indicate that it forms an extended helix.²⁸ Typical of many membrane bound amphipathic helical peptides, δ -hemolysin gives a quite well-resolved one-dimensional ^1H NMR spectrum, with some limitations in the two-dimensional spectrum, resulting from the broad resonance linewidths and efficient spin diffusion. The 32 residue polypeptide hormone calcitonin was characterized in SDS micelles and found to have an amphipathic helix running into the amino terminal disulfide bridged loop.²⁹

The major functional channels in membranes, such as the nicotinic acetylcholine receptor and cation channels, are large oligomeric proteins. Structural studies of these proteins are limited by their overall size and the difficulty in crystallizing them. A promising approach to their analysis is to synthesize and study peptide sequences corresponding to segments of the proteins. We have studied the peptide M2 selected from the δ subunit of the torpedo acetylcholine receptor, because homology and model studies suggest that this sequence-specific motif is responsible for specific functions in the channel activity of the receptor and the 23 residue M2 δ peptide forms channels by self-association when added to membranes. Solution NMR experiments demonstrate that there is substantial helical secondary structure in the M2 δ peptide in micelles.³⁰

Many membrane interactive peptides have antibiotic activities. Cecropin A, a 37 residue peptide found in *Hyalophora cecropia* and other insects, is part of their defense mechanism against bacteria. NMR studies show that this peptide is essentially a random coil in aqueous solution. This peptide has also been studied in hexafluoroisopropyl alcohol solutions by NMR spectroscopy.^{31,32} Interproton distance restraints determined by nuclear Overhauser enhancement measurements and distance restraints hydrogen bonds were used as a basis for three-dimensional structure determination by simulated annealing. The resulting converged structures indicate that there are two α -helical regions extending from residues 5–21 and 24–37. Magainins are a family of 21–26 residue peptides that protect frogs from infections, even after severe injury, with a broad spectrum of antibacterial and antifungal activities. These peptides interact strongly with bacterial and model membranes. Their antibiotic activity appears to be associated with the disruption of the electrochemical ionic gradient across cell membranes. Multidimensional solution NMR spectra, as shown in Figure 2, indicate that magainins are unstructured in aqueous solution, but completely α -helical in detergent micelles³³ and trifluoroethanol/water solutions.³⁴

Adenosine 5'-triphosphate (ATP) synthase consists of two main components; the water soluble complex F_1 , and the membrane-bound complex F_0 . The latter, in turn, consists of three subunits (a, b and c), all of which are needed

Figure 2 Amide region of two-dimensional $^1\text{H}/^1\text{H}$ NOE spectrum of magainin-2 in micelles

for the maintenance of proton pumping. Subunit c is the smallest (79 amino acids) and most abundant subunit. The structure of subunit c dissolved in mixed organic solvents has been investigated by multidimensional solution NMR spectroscopy. The secondary structure was determined from a combination of homonuclear NOE connectivities, and coupling constant measurements. The protein consists of two long and predominantly helical segments separated by a mobile, unstructured, eight residue stretch. The amino and carboxyl termini are close together, such that the molecule is folded in a hairpin arrangement.^{35–37}

Bacteriorhodopsin, the principal component of the outer membrane of *Halobacterium halobium*, where it serves as a light-driven proton pump, is one of the most intensively studied membrane proteins. It consists of 248 amino acids and its structure is dominated by seven transmembrane hydrophobic helices. The protein binds a retinal chromophore to absorb light and translocate protons across the membrane. Solution NMR spectroscopy has been useful in characterizing the structure of bacteriorhodopsin. Fragments corresponding to several of the transmembrane helical sections have been obtained by proteolytic cleavage or peptide synthesis, and have been studied in both organic solvents and detergent micelles. For example, the 34–65 fragment peptide, corresponding to the membrane spanning segment B, was investigated in SDS micelles where it was found to adopt a right-handed helix from residues 41 to 62 with a kink at residue 50, and a disordered amino terminus from residues 34 to 40.³⁸ The longer 163–231 fragment peptide, corresponding to the transmembrane segments F and G, was also investigated in a similar fashion and found to contain extensive regions of right-handed helix and a flexible amino terminus.³⁹

4 SOLID STATE NMR SPECTROSCOPY OF MEMBRANE PROTEINS IN LIPID BILAYERS

Polypeptides that are strongly associated with phospholipids are well suited for solid state NMR spectroscopy,^{30,40,41} because their structured regions are essentially completely

immobilized on the timescales defined by the spectral ranges (10^3 – 10^6 Hz) of the chemical shift, dipolar, and quadrupolar spin-interactions of the nuclei present in proteins. This immobilization preserves the anisotropic characteristics of the nuclear spin interactions averaged out by the rapid isotropic reorientation that occurs in solution, including proteins in micelles. Since it is possible to prepare both oriented and unoriented samples of proteins in fully hydrated phospholipid bilayers, many different parameters can be resolved and measured from single line and powder pattern spectra.

In solid state NMR spectroscopy rf irradiation supplemented by mechanical sample spinning or orientation replace molecular motions as line-narrowing mechanisms. Not only do solid state NMR methods give spectra with high-resolution and sensitivity, they also enable measurements of distance and orientational parameters. There are two complementary methods for protein structure determination by solid state NMR spectroscopy. In one approach, orientational constraints for bonds and chemical groups are derived from spectral parameters observed in samples of peptides and proteins embedded in lipid bilayers oriented between glass plates.⁴² In the other approach, unoriented or powder samples examined in the presence of magic angle sample spinning employ procedures to preserve the dipolar couplings so they can be used for distance measurements.^{43,44}

Very favorable spectroscopic properties are associated with uniaxially oriented samples where the axis of molecular orientation lies parallel to the direction of the applied magnetic field.⁴⁵ Spectra from these samples consist of single line resonances (or multiplets) rather than powder patterns from each isotopically labeled site. Since the observed resonance frequencies (or splittings) are directly related to the orientations of individual atoms or bonds relative to the axis defined by the direction of the applied magnetic field, spectroscopic measurements on oriented samples provide the basis for protein structure determination. The nuclear spin interactions provide spectral parameters that vary as a function of the angle between a bond (or a chemical group) and the direction of the applied magnetic field.

High-resolution structures can be determined with two or more spectroscopic measurements for each structural element, such as a peptide plane or indole ring, since each orientation can be related to a common axis defined by the direction of macroscopic molecular orientation and the applied magnetic field.⁴⁶ The orientational constraints together with the established covalent geometry of the molecule are sufficient to define the complete three-dimensional structure. Limited but worthwhile orientational information can be derived from single spectroscopic measurements on oriented samples.⁴² Once the secondary structure of a polypeptide segment is established, for example from multidimensional solution NMR experiments on samples in micelles, a single spectral parameter is often sufficient to establish the orientation of a helix relative to the plane of the bilayer, which is especially valuable in studies of membrane proteins where helices are often the dominant secondary structural feature.

The structure of a protein can be determined from the measurement of many short-range distances. Distances can be measured quantitatively between pairs of nuclei with solid state NMR experiments. Magic angle sample spinning enables high resolution spectra to be obtained from unoriented samples; however, since the spinning averages out both the

unwanted broadening from the chemical shift anisotropy as well as the dipolar couplings essential for the measurements, it is necessary to cancel out selectively the effects of the spinning on the dipolar interactions. Different experimental approaches are used depending on whether homo- or heteronuclear dipole–dipole couplings are the source of distance information. This application of solid state NMR spectroscopy is rapidly increasing in popularity for structural studies of a variety of biopolymers, including peptides and proteins in lipid bilayers.⁴⁷

It is possible to arrange for heteronuclear dipole–dipole interactions to be present at locations throughout polypeptides by isotopic labeling, enabling distance measurements between specific sites of interest. Rotational echo double-resonance (REDOR) NMR spectroscopy is a general method for measuring internuclear distances between two different nuclei that utilizes rf pulses at the resonance frequency for one of the types of coupled spins to interfere with the averaging of the dipole–dipole interactions.⁴³ Rotational resonance spectroscopy is also used with magic angle sample spinning to measure weak dipole–dipole couplings,⁴⁴ although, unlike REDOR, it is a homonuclear method measuring distances between the same kind of nuclei. The method depends on special effects that occur when the spinning frequency is an integral multiple of the chemical shift difference between the two labeled sites.

Helical peptides are of interest in studies of membrane proteins because they serve as independent structural or functional entities of monomers, oligomers, or domains of larger proteins associated with membranes. Helical peptides, whether hydrophobic or amphipathic, have been found to adopt either transmembrane or in-plane orientations in bilayers, and solid state NMR experiments on oriented samples are adept at differentiating between these two situations. Once the secondary structure is established as helical, then a single solid state NMR measurement is generally sufficient to determine the orientation of the helix in the bilayer. Both qualitative and quantitative analyses of the orientational parameters have given consistent results in determining transmembrane and in-plane orientations of helices. The ^{15}N chemical shift for labeled amide sites is particularly useful for distinguishing between transmembrane and in-plane orientations of helices because of the convenient orientation of the chemical shift tensor in the molecular frame.⁴² A conformation with the N–H bond approximately parallel to the field, which occurs for a transmembrane helix in oriented bilayers, has a ^{15}N chemical shift with a frequency near $\sigma_{\parallel}$, while a conformation with the N–H bond approximately perpendicular to the field, which occurs for an in-plane helix in oriented bilayers, has a ^{15}N chemical shift with a frequency near $\sigma_{\perp}$. These frequencies are separated by the full breadth of the chemical shift anisotropy powder pattern illustrated with the spectra in Figure 3. For example, the spectrum in Figure 3(c) is from a single ^{15}N labeled amide site in a 23 residue peptide with the sequence corresponding to the M2 helical segment of the δ subunit of the acetylcholine receptor, which has been shown to be helical.³⁰ The M2 peptide is shown to have a transmembrane orientation (Figure 4) because its ^{15}N resonance frequency is near the low frequency (high field) ($\sigma_{\parallel}$) edge of the powder pattern. This orientation is consistent with the model for its functioning as a channel by oligomerization within the bilayers.

Figure 3 (a,b) Experimental solid state ^{15}N NMR spectra of 23 residue amphipathic peptides in oriented bilayers. (a) ^{15}N Ala-labeled magainin-2. (b) ^{15}N Ala-12-labeled M2 δ peptide. (c) Simulation of the powder pattern for an immobile ^{15}N amide site

Figure 4 Schematic drawing of in-plane (magainin-2) and transmembrane (M2 δ) orientations of 23-residue amphipathic helical peptides in lipid bilayers. The helical backbones are represented by their 22 peptide bond planes, whereas the white boxes indicate the extending side chains

Contrast the position of the ^{15}N resonance from the M2 transmembrane peptide in Figure 3(b) to that from the magainin-2 peptide in Figure 3(a), which has a ^{15}N resonance frequency near the high frequency ($\sigma_{\perp}$) edge of the powder pattern. This large 170 ppm difference in resonance frequencies is due solely to the difference in orientations of the peptides in the bilayer. Magainin antibiotic peptides from frog skin have been investigated by solid state NMR spectroscopy in lipid bilayers. Their secondary structure has been demonstrated to be a helical by a variety of methods, including solid state NMR spectroscopy.⁴⁸ Spectra, such as that shown in Figure 3(b), from many labeled sites indicate that these peptides are oriented through their entire length in the plane of the bilayers, as shown in Figure 4. In other experiments the heteronuclear dipole–dipole splittings associated with the labeled sites have been measured, providing a second spectral parameter for each site. This enabled the structural determination of four contiguous residues of magainin-2 based only on solid state NMR experiments of oriented samples.

The α -helical secondary structure is in complete agreement with that determined by a variety of other methods, including multidimensional solution NMR spectroscopy in micelles. However, solid state NMR spectroscopy of oriented bilayer samples is unique in being able to determine the in-plane orientation of the helix in the bilayer.

Rotational resonance spectroscopy has been used to measure the distances between ^{13}C labeled sites in peptides with sequences corresponding to the transmembrane domain of glycoporphin A protein in lipid bilayers.⁴⁹ These measurements indicate a helical geometry throughout the peptide, with some evidence of unraveling of the helix near the membrane surface. Measurements have also been made of the distances between sites on the lipids and on the peptides, indicating the feasibility for using these methods to characterize fundamental peptide–membrane interactions.⁵⁰

Gramicidin A is a linear polypeptide of 15 amino acid residues having alternating D and L stereochemistry. As an amino terminus to amino terminus dimer, gramicidin forms a monovalent cation selective channel across lipid bilayers and natural membranes. The channel conformation is a β -strand that forms a helix with 6.3 residues per turn. Solid state NMR spectra of oriented samples provide very high resolution constraints, making it possible to define each peptide plane orientation with respect to the magnetic field. By combining data from adjacent planes and the tetrahedral geometry of the C- α atom, the $\Phi\Psi$ torsion angles can be determined.⁵¹ Considerable effort has been devoted to a characterization of the gramicidin side-chain conformation and dynamics,^{52,53} in particular to the four indole groups per monomer.^{54,55} The orientation for each indole ring with respect to the channel axis and bilayer normal has been determined. This information contributes to models for the roles of indoles in channel conductance. REDOR has been used to measure the dipolar coupling between the Gly-2 ^{13}C -1 carbon and Ala-3 ^{15}N amide nitrogen atom in a sample of gramicidin where the peptide was in lipid bilayers.⁵⁶ This effective coupling was used to determine the orientation of this bond with respect to the bilayer normal. A significant feature of these measurements is that they give the magnitude and sign of the dipolar coupling, enabling the angle to be reduced to a single value and its supplement. This information about the Gly-2-Ala-3 ^{13}C – ^{15}N peptide bond angle was consistent with the data obtained from orientational constraints, showing that gramicidin is a right-handed, single-stranded β -helical dimer in lipid bilayers.

Bacteriorhodopsin has been used in the development of many methods, including solid state NMR spectroscopy,⁵⁷ for probing the structures of membrane proteins. The configuration of the single molecule of retinal bound to bacteriorhodopsin and involved in its mechanism of action is the key to understanding its chemical mechanism. Watts and co-workers have labeled both ring⁵⁸ and individual methyl groups⁵⁹ along the retinal moiety with ^2H . From oriented preparations and the resulting orientational constraints a detailed picture of the bound chromophore conformation has been established. These results add to the large number of prior studies of the retinal with rotational resonance methods. Rotational resonance methods have also been used to measure distances between sites on the retinal chromophore and protein residues.⁶⁰ By utilizing the ^{13}C -labeled retinals and ^{13}C - ϵ lysine labeled bacteriorhodopsin, it was possible to take advantage of the

unique chemical shift of the C- ϵ atom of the lysine involved in the Schiff base.

5 NMR STUDIES OF THE MEMBRANE BOUND FORM OF FILAMENTOUS BACTERIOPHAGE COAT PROTEIN

The membrane bound filamentous bacteriophage coat protein is a small, but typical membrane protein with both amphipathic and hydrophobic helices. It has been the subject of extensive NMR studies in both micelle and bilayer samples and provides an excellent system to illustrate what can be done by combining results from both of these methods. fd is a filamentous bacteriophage that infects *Escherichia coli* and has approximately 2700 copies of a 50 residue major coat protein surrounding its DNA. The viral coat protein is synthesized with an amino terminal signal sequence which directs it to the bacterial inner membrane before being removed by cleavage with leader peptidase. The coat protein becomes the most abundant membrane in infected cells, and then subunits assemble to form the outer coat of the virus particles as they are extruded through the membrane.

fd coat protein in micelles was the first protein shown to have such heterogeneous backbone dynamics that resonances from mobile residues could be clearly distinguished from the rigid residues on the basis of multiple relaxation parameters. Initially, about eight of the backbone C- α resonances were observed to have much narrower linewidths, longer T_1 values, and larger heteronuclear NOEs than the rest of the C- α resonances in natural abundance ^{13}C NMR spectra of fd coat protein in SDS micelles.⁶¹ The presence of mobile amide backbone sites near the amino and carboxyl termini in the membrane bound form of fd coat protein was also shown with ^{15}N -labeled samples in micelles by the observation of large negative heteronuclear $^1\text{H}/^{15}\text{N}$ NOEs and in bilayers with the observation of narrow isotropic resonance intensity in ^{15}N solid state NMR spectra.⁸ The observation of narrow ^{13}C resonance linewidths for some carbonyl sites confirmed that the coat protein had mobile backbone sites in micelle samples.⁶² Additional evidence for mobile residues comes from labeled side-chain sites with the observation of isotropic resonance intensity in ^2H solid state NMR spectra of samples in bilayers⁶³ and with the analysis of the relaxation properties of $^{13}\text{CH}_3$ labeled alanine residues.⁶⁴

Additional evidence concerning protein backbone dynamics comes from the kinetics of hydrogen exchange at amide sites; however, these data are more difficult to interpret directly in terms of protein structure and fluctuations. There are substantial qualitative differences in the exchange rates of amides in different parts of the protein.^{61,65} The exchange rates of individual amide sites throughout the protein have been measured;⁶⁶ the finding was that residues 28 and 45 undergo very slow exchange, while residues 7 and 20 exchange more rapidly, although not nearly as fast as for unstructured solvent exposed sites.

The determination of the secondary structure of fd coat protein in SDS micelles utilizes multidimensional NMR spectroscopy.^{66–68} The majority of the sequential assignments of the amide resonances were made using homonuclear ^1H NOE data from two- and three-dimensional NOE/HMQC

Figure 5 Three-dimensional ($^1\text{H}/^{15}\text{N}$ HMQC/ $^1\text{H}/^1\text{H}$ NOE) solution spectrum of uniformly ^{15}N labeled fd coat protein in SDS micelles in solution

experiments as shown in Figure 5, supplemented with information from TOCSY/HMQC experiments, and spectra of selectively ^{15}N -labeled samples.⁶⁷ All the NOE data are consistent with extensive helical secondary structure in the protein; in particular, NOEs are observed between NH–NH($i, i + 1$), NH–C- αH ($i, i + 1$), NH–C- βH ($i, i + 1$), NH–C- αH ($i, i + 3$), and NH–C- αH ($i, i + 4$) for many residues determined to have helical secondary structure. The $^1\text{H}/^1\text{H}$ strips in Figure 6 at ^{15}N chemical shifts corresponding to S13, L14, and Q15 show the presence of NOEs between resonances from hydrogen atoms on adjacent amide nitrogens, and α - and β -carbon atoms; these residues are part of an amphipathic helix that lies in the plane of the lipid bilayer. K40, L41, and F42 also exhibit these characteristic NOEs and are a part of

Figure 6 Strips taken from the three-dimensional spectrum shown in Figure 5

Figure 7 Solid state ^{15}N NMR spectra of uniformly and selectively ^{15}N -labeled fd coat protein in phospholipid bilayer samples. (a) Uniformly ^{15}N -labeled fd coat protein in bilayers oriented between glass plates. (b) Uniformly ^{15}N -labeled fd coat protein in unoriented bilayers. (c) Selectively ^{15}N -labeled fd coat protein in bilayers oriented between glass plates. (d) Selectively ^{15}N -labeled fd coat protein in unoriented bilayers. (e) Selectively ^{15}N -labeled fd coat protein in bilayers oriented between glass plates. (f) Selectively ^{15}N -labeled fd coat protein in unoriented bilayers

the hydrophobic transmembrane helix. The numerous NOEs observed for residues 13–15 and 40–42 are between $\text{NH}-\text{C}-\alpha\text{H}(i, i + 3)$ and $\text{NH}-\text{C}-\alpha\text{H}(i, i + 4)$ sites, and strongly support the presence of helical secondary structure for these residues. The absence of NOEs for residues 1–5 at the amino terminus of the coat protein indicates that these residues do not participate in stable secondary structure, and the strip from the NOE/HMQC experiment (corresponding to G3 in Figure 8 below) has no NOEs to any other residue. Residues 1–5 are highly mobile, as seen in relaxation data of the coat protein in micelle samples.⁸

The ^{15}N chemical shift powder patterns from unoriented samples of uniformly [Figure 7(b)] and selectively ^{15}N -labeled fd coat protein in lipid bilayers [Figure 7(d)] establish that the membrane bound form of the protein has both mobile and rigid backbone sites. The amide groups of both L14 and L41 are immobile in membrane bilayers because the powder pattern spectrum in Figure 7(d) shows little evidence of motional averaging. However, the spectrum in Figure 7(b) from the uniformly ^{15}N -labeled sample has substantial isotropic intensity from the mobile amino and carboxyl terminal residues.

^{15}N solid state NMR spectra of selectively ^{15}N -labeled coat proteins in unoriented phospholipid bilayers and in oriented phospholipid bilayers are shown in Figure 7(d) and (c), respectively. The comparison of these spectra shows the effect of sample orientation; the two ^{15}N resonances go from a broad, characteristically shaped powder pattern to narrow, single lines with frequencies determined by the orientation of the peptide planes with respect to the direction of the magnetic field. Comparison of the spectra in Figure 7(a) and (b) also shows the effect of sample orientation, although at lower resolution because of multiple overlapping resonances in the uniformly ^{15}N -labeled samples. However, the resonance bands occur at the positions expected for transmembrane and in-plane helices. Since the secondary structure for the two leucine residues is established as helix by the NOE data in Figure 6, the resonance frequency of each nitrogen site can be used to establish the orientations of the helices relative to the plane of the bilayer. The spectrum of ^{15}N -labeled

Figure 8 Model of the membrane-bound form of fd coat protein. The amphipathic helix is parallel to the plane of the bilayer, the hydrophobic helix spans the membrane, and the terminal residues and bend are mobile

coat protein in oriented bilayers [Figure 7(c)] has one line with a resonance frequency near $\sigma_{\parallel}$ and a second line with a resonance frequency near $\sigma_{\perp}$, indicating that the hydrophobic helix spans the bilayer because the N–H bond of one of the leucine residues is parallel to the direction of orientation and that the amphipathic helix is in the plane of the bilayer because the N–H bond of the other leucine residue is perpendicular to the direction of orientation.

Figure 8 summarizes the results of the NMR experiments.⁶⁷ The structure and dynamics of the membrane bound form of fd coat protein were determined by combining results from solid state NMR experiments of the coat protein in bilayers with solution NMR results of the coat protein in micelles. The secondary structure of the protein is almost entirely helical, based on the observation of NOEs among all amide resonances from adjacent residues 7–50 and the NOEs between hydrogen atoms on the nitrogen amide and the α -carbon atoms three and four residues away. The orientation of the helical segments were determined by solid state NMR experiments that showed residues in the amphipathic helix lying parallel to the plane of the bilayer and residues in the hydrophobic helix spanning the bilayer. Tyr-21 is located between the two helices; it is structured on short timescales but shows evidence of mobility on the slower solid state NMR timescale, as shown in Figure 7(f). The presence of strong $\text{NH}-\text{NH}(i, i + 1)$ and $\text{NH}-\text{C}-\alpha\text{H}(i, i + 2)$ NOEs, and the mobility of Y21 on slow timescales suggest that it participates in a turn that connects the two helical regions. Residues 1–5 at the amino terminus of the protein are highly mobile based on a variety of relaxation data in micelle samples and motional averaging of lineshapes in bilayer samples. Residues at the carboxyl terminus are also mobile in both bilayer and micelle samples; however, the observation of homonuclear NOEs indicates that helical secondary structure extends through to the carboxyl terminal on some timescales.

The features of the model of the membrane bound form of fd coat protein are similar to those found for the membrane bound form of Pf1 coat protein,⁶⁹ in spite of the absence of sequence homology between these proteins. The structure and dynamics

of the membrane bound forms of both fd and Pf1 coat proteins were characterized by combining the results of solution and solid state NMR spectroscopies. Both proteins consist of helical secondary structure intermixed with mobile termini and loop regions. The helical regions in fd and Pf1 coat protein consist of two segments, with hydrophobic residues forming a transmembrane helix and amphipathic residues forming a helix parallel to the bilayer plane. The two proteins differ most in the extent of mobility of the segment connecting the two helices. The connecting loop residues in Pf1 are highly mobile on both slow (10^{-4} s) and fast (10^{-9} s) timescales with an absence of homonuclear ^1H NOE cross peaks involving the amide resonances for these residues. In contrast, fd coat protein has homonuclear NOE cross peaks throughout the sequence, including the residues involved in the turn connecting the two helices; there is evidence of limited motional averaging for Tyr-21.

6 PROSPECTS FOR NMR STUDIES OF MEMBRANE PROTEINS

Structural studies devoted to membrane proteins seek to determine their three-dimensional structure and dynamics, with the ultimate aim of integrating these properties into models for their mechanism of action within the natural environment of the biological membrane. Since the structure and function of membrane proteins are intimately related to their hydrophobic membrane environment, serious investigations of these species must, at some stage, focus on the entire supramolecular assembly. NMR spectroscopy has proved itself to be a well suited and sufficiently versatile technique for this purpose, with the micelle and the bilayer samples providing excellent supramolecular model systems for multidimensional NMR solution and solid state NMR studies, respectively. Thus, considering the already large impact of NMR spectroscopy in the membrane protein field, there is good reason to be optimistic that, as the sample preparation and spectroscopic methods are improved, NMR spectroscopy will become generally applicable to the study of membrane proteins.

The development of multidimensional solution NMR spectroscopy of membrane proteins in micelles will be similar to that for larger globular proteins, since the limiting factor, the rotational correlation time, is the same in both cases. The solid state NMR methods that utilize uniaxially oriented samples or implement magic angle sample spinning to achieve resolution, provide measurements of angles and distances between bonds and chemical groups which can be interpreted in terms of structures. The former method has the added advantage of providing details about the orientation of the protein structural elements with respect to the plane of the lipid bilayer. Thus, by using macroscopically and uniaxially oriented membrane samples it becomes possible to distinguish between the case where the protein is membrane spanning and that where the protein associates only superficially with the membrane, or, yet again, where the protein interacts with the bilayer in a wedge-like manner. This is important for understanding the functions of membrane proteins, since they interact asymmetrically with the membrane, imparting different properties to its inner and outer leaflets. The situation is a very different from the more or less isotropic environment of the cell cytoplasm and periplasm

occupied by globular proteins. As a result, NMR spectroscopy has the potential of opening up an entire area of structural biology by providing an added dimension for membrane protein studies.

1 INTRODUCTION

Solid-state NMR spectroscopy is much more than a method for obtaining high resolution NMR spectra of materials that are crystalline, polymeric, aggregated, or otherwise ill-suited for more generally applicable and available solution NMR methods. It is a method for determining the structures of molecules, including those as large and complex as proteins, under the most appropriate conditions, including those where the molecular correlation times are slow. Advances in selective averaging and the measurement of local fields resulting from heteronuclear dipolar couplings were needed to transform this branch of spectroscopy into a full-blown method for structure determination. The local field, which results from the interactions of two or more proximate nuclei, provides a particularly direct source of structural information. Other nuclear spin interactions, especially the chemical shift, also provide valuable structural information, although, their interpretation is generally more complicated and somewhat less firmly grounded. Taken together, the structural constraints resulting from measurements of spectral parameters from several spin-interactions, where at least one of them is a local field, are more than sufficient to determine the three-dimensional structures of complex molecules including proteins.

The experimental demonstration of the local field by Pake in 1948 means that solid-state NMR spectroscopy has been recognized as a method for determining molecular structures for more than 50 years;¹ however, it took until the mid-1970s to develop the methods and instrumentation for structure determination of small organic molecules^{2,3}

and simple polymers.⁴ And only recently has it become feasible to determine the structures of proteins by solid-state NMR spectroscopy. This article discusses the crucial roles of the local field in structural studies of systems that range in complexity from waters of hydration in gypsum¹ and crystalline trichloroacetate⁵ to uniformly isotopically labeled membrane proteins in lipid bilayers.⁶ The combination of heteronuclear dipolar coupling and chemical shift frequencies is shown to be sufficient for characterizing the structures of membrane proteins as a qualitative index^{7,8} as well as through direct calculations of structures from the NMR data.⁹ The approach is illustrated with an example of structure determination of a polypeptide corresponding to a trans-membrane helix of the acetylcholine receptor that functions in membrane bilayers as an ion channel.¹⁰

2 LOCAL FIELD

"The interaction between two nuclear spins depends on the magnitude and orientation of their magnetic moments and also the length and orientation of the vector describing their relative positions."¹¹ As shown in Figure 1, the local magnetic field resulting from the interactions between two nuclear spins is described in a strikingly simple way. With its explicit dependence on a distance and an angle, it provides access to geometrical parameters that can be directly translated into molecular structures. It is also important for experimental spectroscopy, and many of the developments in solid-state NMR spectroscopy have been concerned with the selective averaging of dipolar couplings so that the chemical shift and other spectroscopic parameters can be observed.¹²⁻¹⁶

The attenuation of dipolar couplings is essential because solid-state NMR spectra are typically very broad and overlapped as a consequence of the cumulative effect of the many different local fields. Only in exceptional cases does the material of interest provide sufficient isolation among pairs of spins so that the effects of a single local field can be observed. A doublet with properties described in Figure 1 from the waters of hydration in samples of gypsum was observed by Pake.¹ While the Pake doublet from a polycrystalline sample shown in Figure 2 can be used to determine the internuclear distance between the two hydrogens, the rotation patterns from single crystals enabled the angular dependence to be confirmed and, indeed, for the distance to be measured with greater precision.

Figure 1 The principal factors that affect the splittings observed in solid-state NMR spectra from the dipole-dipole interaction between two nuclei. θ is the angle between the internuclear vector and the direction of the applied magnetic field and r is the distance between the two nuclei

Figure 2 This is Figure 8 from the paper by Pake.¹ The broken line in the upper curve shows the calculated distribution of component line centers for the proton resonance in powdered $\text{CaSO}_4 \cdot \text{H}_2\text{O}$. The continuous line on the same plot is the calculated line shape obtained by superposing Gaussians of width 1.54 gauss according to this distribution function. The lower plot contains experimental points for powdered $\text{CaSO}_4 \cdot \text{H}_2\text{O}$, and a curve which is the derivative of the calculated line shape

Other important topics discussed in this seminal contribution on the local field include the effects of motional averaging and the dominance of homo-nuclear over hetero-nuclear couplings.

Twenty-years after Pake¹ showed that solid-state NMR spectra from samples with chemically isolated pairs of spins could be used to determine molecular structures and Van Vleck¹⁷ discussed the consequences of truncation in NMR experiments, Waugh et al.¹⁵ demonstrated that the severe line-broadening present in chemical samples with normally abundant collections of spins could be selectively averaged with multiple-pulse sequences that could be analyzed in terms of coherent averaging theory.¹⁸ In particular, a pulse sequence was employed that removed the effects of homo-nuclear dipolar couplings while largely preserving the chemical shift effects. Significant parallel developments involved the application of magic angle sample spinning^{12,13} and the demonstration of line narrowing by irradiation arranged by choice of amplitude and frequency-offset to place the magnetization at the magic angle with respect to the magnet field.^{14,19} Thorough analysis of multiple-pulse and other line-narrowing procedures led to a thorough understanding in terms of coherent averaging theory as well as improvements in the sequences themselves.^{18,20–24} Multiple-pulse sequences offer the important advantage of being able to sample the magnetization in the windows between the pulses. The high duty cycle of

the Lee-Goldburg procedures, especially when implemented with phase- and frequency-alternation^{25–27} has led to its use in many multi-dimensional hetero-nuclear experiments where the signals from the dilute rather than the abundant spins are observed.²⁸

The development of double-resonance cross-polarization methods^{16,29} enabled solid-state NMR spectroscopy to shift its emphasis to the “dilute” spins, such as ^{13}C and ^{15}N . Heteronuclear decoupling is easier to implement experimentally and can be accomplished without the scaling (reduction) of chemical shift frequencies that accompanies multiple-pulse line narrowing of ^1H resonances. It is possible to study polycrystalline samples with the use of magic angle sample spinning.³⁰ However, there is a second way to obtain high resolution chemical shift spectra of solid samples that involves the use of single crystals where the molecules have only one or a few orientations relative to each other and the applied magnetic field. Fortunately, it is not necessary to have a single crystal sample. One direction of molecular orientation is sufficient, as long as it is parallel to the magnetic field, to give all of the spectroscopic benefits of sample orientation.⁴ Typically, it is much easier to prepare uniaxially oriented samples of many materials, including proteins in biological supramolecular structures like membrane bilayers, than single crystals for X-ray diffraction or even rapidly reorienting solutions for NMR spectroscopy.

The samples can take the form of drawn fibers, magnetically oriented liquid crystals, or phospholipid bilayers mechanically oriented between glass plates. In uniaxially oriented samples, each site on one molecule can be transformed into the identical site on another molecule through a combination of translation, inversion, and rotation operations about an axis parallel to the direction of the applied magnetic field. Just as observed for single crystals, the spectra of oriented protein samples are characterized by narrow single line resonances rather than powder patterns. The resonance frequencies reflect the orientations of the individual groups, and the geometrical dependencies of the chemical shift, heteronuclear dipolar, and quadrupolar interactions are well characterized. As a result, the solid-state NMR spectra of oriented samples are a rich source of structural information.

3 SEPARATION OF LOCAL FIELDS

The spectroscopic separation of effects from the chemical shift and heteronuclear dipolar interactions are manifested in several different ways in solid-state NMR experiments. This can be appreciated by considering that both the build-up of signal intensity through cross-polarization and the observation of decoupled signals depend on quite different manipulations of the heteronuclear dipolar couplings. There are additional opportunities to observe the effects of heteronuclear dipolar couplings in more complex experiments.

Transient oscillations are observed in the rates of build-up of the intensities of the dilute spin signals as they are developed through spin-lock cross-polarization.³¹ These oscillations have characteristic frequencies that reflect the magnitude of the heteronuclear dipolar coupling that provides the mechanism for transfer of magnetization from the abundant ^1H spin to the dilute ^{13}C or ^{15}N spin.³² Since the dilute spin signals are detected under high-resolution conditions, the signals from individual molecular sites are resolved. This is most

obvious in the spectra of single crystal samples. However, it is also the case for polycrystalline samples where the chemical shift powder pattern discriminates among spins with different orientations with respect to the applied magnetic field, consistent with the representation in Figure 1. Vaughan and coworkers⁵ utilized the modulation of chemical shift spectra by the effects of heteronuclear dipolar interactions of polycrystalline solids.

While most attention has been paid to heteronuclear couplings, as described above, there are situations when the homonuclear couplings are of interest. This is the case for both abundant and dilute spins, and their definitions can overlap with the use of uniformly ^{13}C and ^{15}N labeled proteins. The original work of Pake demonstrated the value of the homonuclear dipolar coupling and that it was spectroscopically accessible with a chemically dilute sample. Stoll et al.⁵ demonstrated a multiple pulse experiment that incorporated two separate time incrementations. This experiment is quite interesting in that it is basically the reverse of what would be used in many subsequent multi-dimensional experiment involving heteronuclear dipolar couplings. Here the first interval is used for the evolution of the homonuclear dipolar interaction, and then the multiple-pulse sequence is applied and data acquired in the usual way in the windows. In this study, the dipolar modulated chemical shift powder patterns were analyzed by comparison to calculations based on the established properties of the molecule. As suggested by the one-dimensional ^1H NMR spectrum with great similarity to the Pake doublet in Figure 2, the Fourier transformation of signals in both time dimensions was about to have its enormous impact on all types of spectra, including those that separate the homonuclear dipolar Pake doublet from the chemical shift powder pattern in polycrystalline samples. Since both the chemical shift and dipolar coupling frequencies depend on orientation, hydrogens with different chemical shifts have different dipolar couplings. The first use of the Fourier transform to analyze the frequencies of the dipolar oscillations during cross-polarization

Figure 3 This is Figure 2 from the paper by Hester et al.² Contour plot of function $f(\omega_1, \omega_2)$. Dipolar splittings for each of the observed seven lines are indicated by the heavy lines. The line bisecting the splittings is the locus $\omega_1 = \omega_2 = \Delta\nu$

Figure 5 This is Figure 2 from the paper by Ramamoorthy et al.³⁵ Experimental three-dimensional ^1H chemical shift/ ^{15}N - ^1H heteronuclear dipolar coupling/ ^{15}N chemical-shift correlation spectra of ^{15}N -acetyl-leucine. (A) Polycrystalline sample. (B) Single-crystal sample

Figure 6 This is Figure 3 from the paper by Wu et al.²⁸ Orientation of the principal axes of the amide ^1H chemical shift, ^1H - ^{15}N dipolar, and ^{15}N chemical shift interaction tensors in a peptide bond

is viewed from the ^{15}N chemical shift/ ^1H - ^{15}N dipolar coupling plane it has a characteristic low-intensity “hole” that is a consequence of the marked noncolinearity of the ^{15}N chemical-shift tensor and the N-H bond axis, as shown in Figure 6.²⁸

The resolution available by applying the three-dimensional pulse sequence diagrammed in Figure 4 to the most crowded spectral regions of a protein is illustrated in Figure 7.³⁶ The sample is uniformly ^{15}N labeled fd coat protein in oriented lipid bilayers. This polypeptide has two major classes of resonances because it has a *trans*-membrane helix and a shorter in-plane helix that resolute in the vast majority of residues having similar backbone orientations with their N-H bonds either parallel or perpendicular to the field. However, the ^1H chemical shift separated two-dimensional ^1H - ^{15}N dipolar coupling/ ^{15}N chemical shift planes display excellent resolution.

5 PISA WHEELS

On the path toward three-dimensional structure determination, the secondary structure and topology of membrane proteins can be described by inspection of the two-dimensional

$^1\text{H}/^{15}\text{N}$ PISEMA spectra of uniformly ^{15}N -labeled samples in oriented bilayers. The characteristic ‘wheel-like’ patterns of resonances observed in these spectra reflect helical wheel projection of residues in both transmembrane and in-plane helices and hence provide direct indices of secondary structure and topology of membrane proteins in phospholipid bilayers. We refer to these patterns as PISA (polarity index slant angle) wheels.^{7,8} The resonance frequencies in PISEMA spectra of oriented samples or membrane proteins depend on helix orientation, as well as on the backbone dihedral angles, the magnitudes and orientations of the principal elements of the amide ^{15}N chemical shift tensor, and the NH bond length. Therefore, it is possible to calculate solid-state NMR spectra for specific structural models of proteins, as shown in Figure 8.

When the helix axis is parallel to the bilayer normal all of the amide sites have an identical orientation relative to the direction of the applied magnetic field, and therefore all of the resonances overlap with the same dipolar coupling and chemical shift frequencies. Tilting the helix away from the membrane normal breaks the symmetry, introducing variations in the orientations of the amide NH bond vectors relative to the field. This is manifest in the spectra as dispersions of both the ^1H - ^{15}N dipolar coupling and the ^{15}N chemical shift frequencies. Since a modest helix tilt of about 10° aligns the NH bond from one amide site and the σ_{33} amide ^{15}N chemical shift tensor element of another amide site with the magnetic field, the maximum values of both of these frequencies are observed in the spectrum, albeit from different amide resonances because σ_{33} of the shift tensor is rotated approximately 17° from the NH bond vector, as shown by the low-intensity region of the spectrum in Figure 6. Nearly all transmembrane helices are tilted with respect to the bilayer normal, and it is the combination of the tilt and the 17° difference between the direction of σ_{33} and the NH bond vector that makes it possible to resolve many resonances from residues in otherwise uniform helices and is responsible for the ‘wheel-like’ pattern in PISEMA spectra. For all helix orientations other than parallel to the field (0°), the spectra have ‘wheel-like’ patterns whose frequency breadths, especially in the dipolar coupling dimension, reflect the extent of helix tilt. For helices with tilts greater than 40° some amide NH bonds adopt orientations near the magic angle (55°) with respect to the direction of the magnetic field and have resonances with dipolar couplings of close to 0 kHz. Other

Figure 7 This is Figure 3 from the paper by Marassi et al.⁶ Two-dimensional $^1\text{H} - ^{15}\text{N}$ heteronuclear dipolar coupling/ ^{15}N chemical shift spectral planes from spectra of an oriented sample of uniformly ^{15}N -labeled fd coat protein in phospholipid bilayers. (A. and D.) expansion of the complete two-dimensional PISEMA spectrum of the protein. A is the trans-membrane helix region and D is the in-plane helix region. (B) Plane extracted from the three-dimensional correlation spectrum at ^1H chemical shift 7.4 ppm. (C) Plane extracted from a three-dimensional correlation spectrum at ^1H chemical shift 11.0 ppm; the resonance assigned to Leu-41 is marked. (E) Plane extracted from a three-dimensional correlation spectrum at ^1H chemical shift 12.5 ppm. (F) Plane extracted from a three-dimensional correlation spectrum at ^1H chemical shift 11.6 ppm; the resonance assigned to Leu-14 in the amphipathic in-plane helix is marked

amide NH bonds are oriented with angle greater than 55° and have resonances with dipolar couplings of opposite sign, which results in a portion of the ‘wheel-like’ PISEMA spectrum being reflected through the 0 kHz axis. Figure 8 shows that helices oriented parallel to the membrane surface have their amide NH bonds and σ_{33} of the ^{15}N chemical shift tensor nearly orthogonal to the field and give highly overlapped spectra with all of the resonance frequencies around 5 kHz and 75 ppm. The spectra in Figure 8 demonstrate that it is possible to determine the tilt of a helix in lipid bilayers without resonance assignments.

In the experimental PISEMA spectrum of AchR M2 shown in Figure 9(B), the order of resonances in the ‘wheel-like’ pattern follows that of the helical wheel projection shown in Figure 9(A). The helical wheel is arranged so that the residues align with their corresponding amide resonances, as predicted by the simulated spectrum in Figure 9(C). The polarity of the ordering of resonances in the ‘wheel-like’ pattern in a

PISEMA spectrum provides a direct measure of the angle of helix rotation (polarity index) about its long axis within the membrane. In principle, only a single assignment is needed to determine the polarity of a helix in the membrane. This example is based on an ideal helix. Deviations from ideal Ramachandran angles that result in local kinks or long-range bends can be readily accommodated within this framework.

6 CALCULATIONS FOR PROTEIN STRUCTURE DETERMINATION FROM SOLID-STATE NMR DATA

In principle, a single three-dimensional correlation spectrum of an oriented sample of a uniformly ^{15}N labeled protein provides sufficient information for complete structure determination. The three frequencies, ^1H chemical shift, ^{15}N chemical

Figure 8 This is Figure 1 from the paper by Marassi and Opella.⁷ PISEMA spectra calculated for a 19-residue α -helix with 3.6 residues per turn and uniform dihedral angles ($\phi = -65^\circ$, $\psi = -40^\circ$) at various helix tilt angles relative to the bilayer normal

shift, and $^1\text{H}/^{15}\text{N}$ dipolar coupling, measured for each resonance depend on the magnitudes and orientations of the principal elements of the spin-interaction tensors in the molecule, and on the orientation of the molecular site with respect to the direction of the applied magnetic field. Because the orientation of the bilayer is fixed by the method of sample preparation, each frequency reflects the orientation of a specific site in the protein with respect to the bilayer. Structures are calculated using the angular constraints extracted from the measured spectral frequencies. Using this approach determined the three-dimensional structure of the M2 transmembrane segment from the acetylcholine receptor, as described below.¹⁰ The ^{13}C

chemical shift and the ^2H quadrupolar coupling frequencies, measured from selectively or specifically labeled samples in separate experiments, also provide valuable structural information, and have been used together with the ^{15}N chemical shift and the $^1\text{H}/^{15}\text{N}$ dipolar coupling, to determine the structure of the gramicidin channel at high resolution.³⁸

The backbone structure of a protein is defined by the planes formed by the individual rigid peptide bonds and their directly bonded atoms. This is equivalent to the conventional description by vectors representing bonds between non-hydrogen atoms. A standard planar peptide geometry serves as the building block for the structure assembly process. The orientation of a peptide plane consistent with the measured NMR frequencies is defined in terms of polar angles relative to the magnetic field. The inputs to the computer program are the NMR frequencies measured from a three-dimensional correlation spectrum, and the values of the amide ^{15}N and ^1H chemical shift tensors. Once the orientations of all the peptide planes in the protein are calculated, neighboring planes of fixed orientation are connected through their common α -carbon atom, with the only constraint of a fixed tetrahedral angle of 110° . Another program calculates the phi and psi dihedral angles for the two contiguous peptide plane combinations that satisfy tetrahedral angle geometry at the α -carbon. The advantage of this direct mathematical analysis is that it is possible to determine the standard deviations in phi and psi based on uncertainties in the experimentally determined angles. Another important advantage of the method is that it results in the 'piece-wise' assembly of structures. Different parts of the protein structure can be determined independently of the rest. This is not possible in methods where distance constraints between different regions of the protein must be established for three-dimensional structure determination. Because the orientation of individual peptide planes is determined relative to a unique external reference the corresponding errors are not cumulative.

7 APPLICATION TO THE THREE-DIMENSIONAL STRUCTURE OF THE ACETYLCHOLINE M2 PEPTIDE IN LIPID BILAYERS

The three-dimensional structures of functional peptides corresponding to the M2 segments from the α -subunit of the Acetylcholine receptor (AChR) and the NR1 subunit of the NMDA subtype glutamate receptors were determined by solution and solid-state NMR spectroscopy in membrane environments.¹⁰ The relatively large quantities of isotopically labeled M2 peptides required for NMR spectroscopy were prepared by expression of recombinant peptides in *E. coli*, for selective or uniform isotopic labeling, and by solid-phase synthesis, for specifically labeled samples.

The incorporation of the M2 peptides into lipid bilayers reconstitutes functional, cation-selective channels. The single channel currents recorded from AChR M2 in lipid bilayers, under voltage clamp conditions have heterogeneous conductances and lifetimes, as expected for monomeric peptides that self-assemble into conductive oligomers of discrete yet variable size, and display a linear current-voltage relationship. The channels that occur most frequently exhibit a single-channel conductance of about 38 pS in both NaCl and KCl. Significantly, the channel properties of peptides prepared by solid-phase synthesis and by expression in bacteria are nearly

Figure 9 This is taken from Figure 2 from the paper by Marassi and Opella.⁷ Helical wheel projection and two-dimensional PISEMA spectra of the uniformly ^{15}N -labeled acetylcholine receptor M2 polypeptide in oriented lipid bilayers. (A) Helical wheel projection of the amide N atoms of the polypeptide. (B) Experimental PISEMA wheel spectrum of the polypeptide, which provided most of the orientational constraints used for structure determination. (C) Spectrum calculated for an α -helix with 3.6 residues per turn, identical dihedral angles ($\phi = -65^\circ$, $\psi = -40^\circ$), and a tilt of 12° relative to the membrane normal

identical. Furthermore, peptides with the same amino acid composition as the M2 but with scrambled sequences do not form channels, nor do peptides patterned after the sequences of the predicted M1, M3 or M4 helices. Taken together, these results indicate that both the recombinant and synthetic M2 peptides used in the NMR experiments are functional, and form sequence-specific, discrete ion-channels in lipid bilayers.

The two-dimensional solid-state $^1\text{H}/^{15}\text{N}$ PISEMA spectrum of the peptide in oriented bilayers (Figure 9B) has excellent resolution, with each amide resonance characterized by ^{15}N chemical shift and $^1\text{H}-^{15}\text{N}$ dipolar coupling frequencies. The ^{15}N chemical shift and $^1\text{H}-^{15}\text{N}$ dipolar coupling frequencies provide orientational constraints for structure determination of ^{15}N labeled peptides in lipid bilayer membranes, and can be

measured directly from the two-dimensional PISEMA spectrum shown in Figure 7(B) for AchR M2. The backbone structure of AchR M2, determined from ^{15}N chemical shift, $^1\text{H}-^{15}\text{N}$ dipolar coupling, and some ^1H chemical shift constraints, is shown in Figure 10. Solid-state NMR on oriented lipid bilayer samples is unique in determining the complete topology, including three-dimensional structure and orientation, of the peptide in the membrane, at high resolution. This is a crucial element of membrane protein structure, and in the case of AchR M2, sheds light on the details of supramolecular channel architecture. The AchR M2 peptide is a transmembrane α -helix with its long helix axis tilted 12° relative to the lipid bilayer normal (88° from the lipid bilayer plane).

Figure 10 shows a model of the AchR channel pore. It was constructed from the three-dimensional structure of the AchR M2 helix derived from solid-state NMR data and the pentameric organization of the channel in lipid bilayers. The optimized pentameric bundle has a right-handed, inter-helical twist with an orientation angle of 12° . A central narrow pore has a diameter ranging from about 3.0 Å to 8.6 Å. Nonpolar residues are predominantly on the exterior of the bundle, while polar residues line the pore. The residues exposed to the pore lumen are Glu-1, Ser-4, Ser-8, Val-15, Leu-18 and Gln-22, which is in agreement with evidence collected from mutagenesis, affinity labeling and cysteine accessibility measurements. A side view shows a funnel-shaped bundle, 33 Å in length, with the wide mouth at the N-terminus. A dotted contour depicting the profile of the ion-conduction pore calculated from the structure is shown. The channel lining hydroxyl residues are in agreement with the expectations of a water-filled pore, and the constrictions are compatible with the permeation of both Na and K ions.

Figure 10 This is taken from Figure 5 from the paper by Opella et al.¹⁰ Top (A) and side (B, C) views of a model of the acetylcholine receptor M2 funnel-like pentameric bundle. The channel architecture was calculated using the three-dimensional coordinates of the M2 helix in the lipid bilayer determined by solid-state NMR spectroscopy, and by imposing a symmetric pentameric organization. (C) is the pore profile

8 SUMMARY

The structure of the polypeptide shown in Figure 10 was determined using solid-state NMR methods that were direct descendants of the initial observations of doublets due to local fields in 1948. The advances required to transform solid-state NMR from a spectroscopic technique to a generally applicable method for determining molecular structures included

multiple-pulse sequences, double-resonance methods, and separated local field spectroscopy. It also required improvements in instrumentation, especially the use of high-field magnets. The pace of development is accelerating, and the local field is being utilized in an increasing number of ways in spectroscopic investigations of molecular structure and dynamics.

1 INTRODUCTION: CHOLESTEROL AND MODEL MEMBRANES

Cholesterol and related structures are distributed ubiquitously in the membranes of living organisms. Cholesterol is a major component of mammalian plasma membranes and plasma lipoproteins. Cell surface membranes, some viral membranes, and specialized cell membranes such as myelin contain large amounts of cholesterol, having as much as equimolar amounts of cholesterol and phospholipids. On the other hand, subcellular membranes tend to have less cholesterol, with the inner mitochondrial membrane having a very low cholesterol content.^{1,2} Cholesterol levels are altered in the membranes of some pathophysiological states such as malignant lymphoid cells.³ Cholesterol plays many important roles in membranes, including modulation of phospholipid packing density, separation of phospholipid headgroups and disruption of interactions between neighboring headgroups, alteration of membrane permeability behavior, and regulation of membrane-bound enzyme activities. Therefore, studies of the interactions between cholesterol and phospholipids and their consequences with respect to membrane structure and function have been the subject of intense scrutiny for more than three decades.^{4–7}

Much of the current understanding of the effects of cholesterol in membranes has come from studies of model bilayer membranes, which are formed by simply dispersing phospholipids, cholesterol, and other compounds in aqueous media. Since the composition of these aqueous dispersions is easily controlled, bilayers prepared from fully hydrated phospholipids have been used extensively in physicochemical studies. This review of the use of NMR for the study of phospholipid–sterol interactions places special emphasis on ²H NMR. The principal topic in this review is the use

of NMR to obtain information about the equilibrium phase behavior of cholesterol–phospholipid mixtures, as expressed in phase diagrams and measurements of the order of the hydrocarbon region of membranes. We also present here a brief review of selected NMR literature on methods employing several nuclei that has led to our current understanding of sterol–phospholipid interactions, together with an overview of differential interactions of cholesterol with a variety of phospholipid subclasses such as ester- and ether-linked phosphatidylcholines (PCs).

2 EARLY WORK ON CHOLESTEROL–PHOSPHOLIPID INTERACTIONS

Some of the earliest work on cholesterol–phospholipid mixtures in model bilayer membranes was carried out using X-ray diffraction and differential scanning calorimetry (DSC) techniques, which produced phase diagrams that were refined as discussed below.^{4,8} These studies led to the concept that cholesterol produces a state of ‘intermediate fluidity’ in a phospholipid by decreasing hydrocarbon chain motion in the liquid crystalline state and increasing the hydrocarbon chain motion in the gel state.⁴ These properties of bilayers were consistent with earlier observations in monolayers that showed that cholesterol ‘condensed’ phospholipids in which there was freedom of chain motion⁹ and expanded phospholipids in which chain motion was restricted.¹⁰ More precise DSC studies led to a partial phase diagram of the dipalmitoylphosphatidylcholine (DPPC)–cholesterol system,¹¹ and partitioning experiments with the spin probe Tempo (2,2,6,6-tetramethylpiperidine-*N*-oxyl) resulted in partial phase diagrams of dimyristoylphosphatidylcholine (DMPC)–DPPC mixtures with parts of the boundaries of the *L_α*, or liquid-disordered (*ld*) and liquid-ordered (*lo*), delineated.¹² Similarly, a partial phase diagram was constructed for DMPC–cholesterol mixtures which included the gel or solid-ordered (*so*), *ld*, and *lo* regions (see below).¹³

The first use of NMR to investigate phospholipid–cholesterol interactions was carried out by Chapman and Penkett,¹⁴ who used continuous wave ¹H NMR to show that cholesterol broadened the resonances of the fatty acyl chains and headgroup of egg PC bilayers above the phospholipid phase transition temperature. Similar information was obtained from other early ¹H and ¹³C NMR studies of various phospholipid–cholesterol mixtures.¹⁵ The first application of ²H NMR to the investigation of model membranes was a study of the effects of cholesterol and temperature on dual-chain perdeuterated DMPC-*d*₅₄ bilayers.¹⁶ Above the phase transition temperature (*T_m*), cholesterol caused the quadrupole splitting of the methylene deuterons to increase, indicative of increased order and reduced motion in the presence of cholesterol. Use of PCs and cholesterol, specifically deuterated at selected sites, provided a wealth of information about the PC–cholesterol system; for references to early ²H NMR studies, see Davis¹⁷ and Vist and Davis.¹⁸ Many of these studies suffered from the drawback that it was not possible to reproduce faithfully the ²H NMR lineshapes, particularly in the gel phase, with the pulsed Fourier transform methods then in use. The introduction of quadrupole echo Fourier transform NMR¹⁹ overcame

this problem and allowed essentially undistorted ^2H NMR spectra to be recorded and detailed phase diagrams to be produced. Application of this technique to examine order and dynamics in deuterated DMPC-cholesterol mixtures²⁰ and other bilayer-forming phospholipids (reviewed in Davis¹⁷) followed quickly. Proton magic angle sample spinning NMR has also been applied to the study of phospholipid-cholesterol interactions.²¹ Recently, ^2H NMR was used to carry out a comprehensive examination of molecular order and dynamics in DMPC-cholesterol mixtures.²²

3 REFINEMENT OF PHOSPHOLIPID-CHOLESTEROL NMR STUDIES

3.1 The Effect of Cholesterol on Phospholipid Acyl Chain Order

The ^2H NMR spectrum of a deuteron on the acyl chain of a phospholipid in the liquid crystalline state of a bilayer with random orientation is an axially symmetric Pake doublet. The sharp edges of the doublet arise from molecules undergoing reorientation about an axis that is perpendicular to the applied magnetic field. The quadrupolar splitting of these 90° edges is

$$\Delta\nu_Q = \frac{3}{4} \frac{e^2 q Q}{h} S_{\text{CD}} \quad (1)$$

where S_{CD} , the orientational order parameter of the carbon-deuterium bond, is given by

$$S_{\text{CD}} = \frac{1}{2} (3 \cos^2 \theta_{\text{CD}} - 1) \quad (2)$$

In equation (2), θ_{CD} is the angle between the carbon-deuterium bond and the applied magnetic field, and the average is over the motions of the bond. In the gel phase, the chains are more highly ordered, so their slower, asymmetric motion results in a broad spectrum with no sharp features. The ^2H NMR spectra of deuterated lipids have been reviewed in Davis.¹⁷

The ^2H NMR spectrum of perdeuterated phospholipids in the liquid crystalline phase of bilayers is a superposition of doublets with a range of splittings reflecting the decrease in orientational order toward the bilayer center. The effect of cholesterol on the chains is illustrated in Figure 1. Above T_m , which is about 38°C for DPPC- d_{62} , addition of cholesterol increases the doublet splittings, indicative of an increase in acyl chain order and bilayer thickness. Below T_m , the spectrum in the presence of cholesterol indicates that the chains are ordered but undergoing axially symmetric reorientation. The result is a superposition of axially symmetric doublets with large splittings.

Incorporation of DPPC- d_{62} (at 25 mol%) into undeuterated egg PC liposomes resulted in the appearance of a plateau region (which reflects the superposition of the quadrupole splittings of the seven or eight CD_2 groups nearest to the glycerol backbone) and a series of peaks for the more motionally disordered segments between the middle of the chain and the terminal CD_3 group.²³ Incorporation of cholesterol (at 50 mol%) increased the peak-to-peak quadrupole splittings by 75–140%, indicative of a more ordered system.

Figure 1 ^2H NMR spectra of DPPC- d_{62} in DPPC- d_{62} -cholesterol (chol) bilayers. Spectra were collected at 23.2 MHz using the quadrupole echo sequence with a pulse separation of $40\ \mu\text{s}$. (a) $x_{\text{chol}} = 0.035$, $T = 40^\circ\text{C}$; (b) $x_{\text{chol}} = 0.16$, $T = 40^\circ\text{C}$; (c) $x_{\text{chol}} = 0.285$, $T = 40^\circ\text{C}$; (d) $x_{\text{chol}} = 0.035$, $T = 35^\circ\text{C}$; (e) $x_{\text{chol}} = 0.16$, $T = 35^\circ\text{C}$; (f) $x_{\text{chol}} = 0.285$, $T = 35^\circ\text{C}$

3.2 The Effect of Analogs of Cholesterol on Phospholipid Acyl Chain Order

3.2.1 ^2H and ^{13}C NMR Studies of the Interaction of Epicholesterol (5-Cholesten-3 α -ol) with PC

NMR and other physical studies have shown that the molecular features required in a sterol for the ability to moderate the angular fluctuations of phospholipids in bilayers are a planar steroid nucleus, a 3β -hydroxy group, and a long apolar side chain at C-17. Deletion of any of these features results in failure of cholesterol to reduce membrane permeability, broaden the gel-to-liquid-crystalline phase transition, or reduce the mean molecular area of phospholipids in monolayers. Sterols with a planar α face interact principally by van der Waals interactions with the phospholipid acyl chains. Lanosterol, which lacks a planar α face since its 14α -methyl group protrudes from this surface, has considerably more mobility than cholesterol in PC vesicles as judged by ^{13}C NMR.²⁴

The relative mobilities of cholesterol and epicholesterol have also been compared in bilayers. The rotational freedom of cholesterol molecules in sonicated phospholipid vesicles can be estimated from spin-lattice relaxation (T_1) and linewidth ($\Delta\nu_{1/2}$) measurements of selected carbon resonances. A comparison of the rotational freedom of cholesterol and epicholesterol in egg PC vesicles was made by ^{13}C NMR as a function of temperature.²⁵ Below 32°C epicholesterol has a broad C-6 resonance of about the same linewidth as the C-6 nucleus of cholesterol, and both sterols have a similar effect on PC dynamics as estimated from their ability to cause similar broadening of the sn -1 carbon but not of the sn -3 carbon. At 41 – 42°C , however, the motion of epicholesterol is less restricted than that of cholesterol in egg PC vesicles, as judged by the observation of resonances from C-9 and C-14,17. These studies provide additional proof that the dynamics of component lipids are relevant to membrane function.

Models have been proposed to explain the molecular basis of the differential effects of epicholesterol and cholesterol on the packing of phospholipids in bilayers. Although both

sterols are oriented with the long axis normal to the bilayer surface, a collinear hydrogen bond may be formed with the 3β -hydroxy group of cholesterol and an acceptor such as one of the carbonyl oxygen atoms of the phospholipid;²⁶ alternatively, the 3β -hydroxy group of cholesterol may be more extensively hydrated than the 3α -hydroxy group of epicholesterol.²⁷ On the basis of ^2H NMR studies with specifically deuterated cholesterol and epicholesterol in DMPC or DMPC- d_{27} bilayers between 10 and 65 °C, a pronounced tilt of epicholesterol with respect to the bilayer normal was evident at physiological temperatures.²⁸ Furthermore, the iso-octyl side chain of cholesterol was found to be as ordered as the steroid nucleus. The quadrupolar splittings of epicholesterol and cholesterol deuterated at C-3 in DPPC bilayers suggested that the angle of tilt of the sterol nucleus relative to the bilayer normal is different in the two sterols.²⁹ Cholesterol was estimated to be inclined at an angle of 16–19° at 24 °C and 60 °C, which is similar to the tilt of the fatty acyl chains in bilayers; thus, the steroid nucleus and the phospholipid fatty acyl chains have a nearly parallel alignment, with the 3β -hydroxy group projecting toward the water and fully accessible for hydrogen bonding. In contrast, the steroid nucleus of epicholesterol was proposed to lie nonparallel to the phospholipid fatty acyl chains at 24 °C. The 3α -hydroxy group was postulated to lie essentially perpendicular to the bilayer normal, accessible to interaction with water, but positioned at an angle that increases the distance between the steroid nucleus and fatty acyl chains, thus diminishing the extent of lipid–lipid interactions and perturbing the packing of the lipid chains. These studies make clear the reason why epicholesterol is not a naturally occurring membrane component; its presence would destabilize bilayers by disturbing close packing of lipid chains.

3.2.2 ^2H NMR Studies of the Interaction of Terpene Alcohols ('Cholesterol Ancestors') with PC

Many polyterpenoid 'ancestors' of cholesterol, although they resemble cholesterol in their rigidity, overall cylindrical shape, and amphiphilic character, generally fail to increase the acyl chain order of phospholipids in fluid phase oriented multilayers, as probed by the increase in mean order parameter using single chain perdeuterated phospholipids such as DMPC- d_{27} and DPPC- d_{31} .³⁰ Thus the molecular dimensions of cholesterol have apparently evolved in a manner that permits this sterol to play an important role in modulating membrane structure, and this sterol became ubiquitous in most eukaryotic cell membranes. Incorporation of cholesterol at 30 mol% increases the order parameter of the plateau region and terminal methyl region by 78% and 130%, respectively.³¹ The extent to which a cholesterol surrogate has the capacity to increase the mean order parameter of oriented bilayers represents a measure of its resemblance to cholesterol.

3.3 Interaction of Cholesterol with Sphingomyelin

There is considerable evidence that the lateral packing density of cholesterol with sphingomyelin is higher than that with PCs (for references, see Bittman³²). However, ^{13}C NMR studies of [4- ^{13}C]cholesterol did not reveal a significant difference in the rotational freedom of cholesterol molecules

in PC and sphingomyelin sonicated vesicles, as estimated by $\Delta\nu_{1/2}$ and T_1 measurements.³³ There is substantial evidence that sphingomyelin bilayers are packed more tightly than PC bilayers of similar degree of acyl saturation. Early ^2H NMR studies of unsonicated bilayers showed that a semisynthetic sphingomyelin labeled with deuterium at C-10 of the amide-linked chain had significantly higher quadrupole splitting ($\Delta\nu_Q$) than DPPC labeled with deuterium at C-10 of the *sn*-2 palmitoyl chain.³⁴ More detailed studies of this system are required with specifically labeled, chemically defined sphingomyelins in order to examine whether the mode of packing of cholesterol differs in sphingomyelin and PC bilayers.

3.4 Interaction of Cholesterol with Ether-Linked Phosphocholines

3.4.1 ^1H NMR Studies with Plasmenylcholine and PC Vesicles

It is of interest to examine the possibility that cholesterol modulates the motional characteristics of the major mammalian choline glycerophospholipids' subclasses in a differential manner. Proton spin–lattice relaxation times and apparent activation energies of T_1 relaxation times for vinyl and bisallylic methylene protons in liquid crystalline bilayers of a diacyl-PC (1-palmitoyl-2-arachidonoyl-3-PC) were higher than that of a plasmenylcholine, 1-*O*-(*Z*)-hexadec-1'-enyl-2-arachidonoyl-3-PC.³⁵ Incorporation of cholesterol resulted in substantial decreases in the proton spin–lattice (T_1) relaxation times in the interior regions of plasmenylcholine bilayers, and this decrease was larger than that in PC bilayers. On the other hand, the T_1 values of the choline methylene protons of plasmenylcholine bilayers were increased on introduction of cholesterol, and this increase was larger than that found in diacyl-PC bilayers.

Although ^2H and ^{13}C NMR studies have shown that polar headgroup motion of phospholipids in multilamellar vesicles is not significantly altered by incorporation of cholesterol,^{13,36} the spin–spin relaxation times (T_2) of CH_2N and $\text{N}-\text{CH}_3$ of both PC and plasmenylcholine sonicated vesicles were decreased by cholesterol (at 30 mol%); also, the T_2 values of the bis-allylic protons of arachidonic acid in PC or plasmenylcholine vesicles were decreased by cholesterol (at 30 mol%).³⁷ These proton spin–spin relaxation time measurements indicate that introduction of cholesterol results in slower motion of the polar headgroup of plasmenylcholine and PC vesicles. Since plasmenylcholine lacks an ester linkage at the *sn*-1 position, yet still has its motional properties altered by cholesterol, these results suggest that hydrogen bonding to an *sn*-1 carbonyl group of diacyl-PC is not required for interaction of phospholipids with cholesterol.

3.4.2 ^{13}C NMR Studies of Saturated Ether-PC and Ester-PC Vesicles

The conclusion stated above is consistent with previous ^{13}C NMR studies of cholesterol enriched with ^{13}C at the 4-position, in which ^{13}C NMR relaxation measurements indicated that no significant relocation of the 4- ^{13}C atom of cholesterol took place when a methylene group was substituted for a carbonyl

group in PC sonicated vesicles.³⁸ The apparent spin-spin relaxation time $T_2 [= (\pi \cdot \Delta \nu_{1/2})^{-1}]$, which reflects mainly slower motions involving reorientation of local segments, for the $4\text{-}^{13}\text{C}$ atom of cholesterol was shorter in bilayers prepared with 1-ester-2-ether-PC or 1,2-diether-PC than in those prepared with 1,2-diester-PC. Thus, the presence of an *sn*-2 *O*-alkyl linkage in PC rather than an *sn*-2 ester linkage appears to result in a relatively restricted motion of cholesterol (present at 10 mol%). In a diester-PC, the arrangement of the *sn*-1 and *sn*-2 chains is different near the lipid-water interface; the ester linkage at *sn*-2 lies at the interface, whereas the *sn*-1 ester linkage penetrates into the bilayer. In PCs having an *sn*-2 *O*-alkyl linkage, the absence of a bend results in tighter packing of PC molecules in this region of the membrane interface, which is reflected in the shorter apparent T_2 values for $[4\text{-}^{13}\text{C}]$ cholesterol in dihexadecyl- and 1-palmitoyl-2-*O*-hexadecyl-PC vesicles. This difference in lipid packing property does not require that formation of a hydrogen bond be postulated between cholesterol and the phospholipid. Indeed, no evidence for such a hydrogen bond was found in recent ^2H NMR studies of 3- $[^2\text{H}]$ -cholesterol in DMPC vesicles.³⁹ However, evidence for a putative hydrogen bond between the 3β -hydroxy group of cholesterol and the *sn*-2 carbonyl of DPPC has been suggested from a high-frequency shift in the ^{13}C NMR spectrum of DPPC carbonyl carbon atoms in the presence of cholesterol.^{40,41}

3.5 Use of Spectral Subtraction for Phase Diagram Determination

Many studies have been directed toward the refinement of phase diagrams of a variety of phospholipid-cholesterol systems by application of a wide range of physical techniques (see, for example, references cited in Vist and Davis¹⁸ and Blume and Griffin⁴²).

In excess water, a system containing two bilayer-forming components can be treated as a binary mixture. It can be shown that along a line of constant temperature in a binary phase diagram, regions corresponding to different homogeneous phases must be separated by regions in which the free energy of the system is lowered by separation into coexisting domains of the adjacent homogeneous phases. One approach to determining the boundaries of such regions of two-phase coexistence is to scan the temperature through the two-phase region, while observing some property that is sensitive to the thermodynamic phase of the sample, such as excess specific heat in a DSC experiment or lineshape in an NMR experiment. When carried out for a series of sample concentrations, this type of experiment indicates the upper and lower temperature limits of two-phase coexistence for a particular composition.

In order to describe the way in which spectral differences are used in phase diagram studies, we consider here a two-component bilayer system with a temperature and composition that falls within a region of two-phase coexistence in the binary phase diagram. We will use x to denote the mole fraction of component 2 in the bilayer. For the purpose of this discussion, we will take the coexisting phases to be a phase G with a lower concentration of component 2 and a phase F , which is richer in component 2. If, at a particular temperature T , the composition x falls within the two-phase region, the mixture will separate into domains of G and F , with compositions that

correspond to the points at which an isotherm at temperature T intersects the boundaries of the two-phase region. These points are referred to as endpoints. For the example described here, the gel-phase boundary composition at temperature T is labeled $x_G(T)$, and the fluid-phase boundary composition is labeled $x_F(T)$. If component 2 lowers the $G \rightarrow F$ transition temperature, then we have $x_F(T) > x_G(T)$. The partitioning of the sample between the coexisting phases is determined by the lever rule. For example, the fraction of the sample in the F phase will be given by

$$f_F(x, T) = \frac{x - x_G(T)}{x_F(T) - x_G(T)} \quad (3)$$

Consider the situation where one of the components is deuterated. We will take component 1 to be the labeled component. The endpoint concentrations can be determined if exchange between domains of the coexisting phases is slow on the ^2H NMR timescale.⁴³ Under these circumstances, the observed spectrum $S(x)$ for a sample of composition x in the two-phase coexistence region, at a particular temperature, will be a superposition of spectra S_G and S_F , corresponding to the endpoint compositions at that temperature. If $S(x)$, S_G , and S_F are normalized to a constant area, then the observed spectrum is given by

$$S(x) = \frac{(1 - x_G)(x - x_F)}{(1 - x)(x_G - x_F)} S_G + \frac{(1 - x_F)(x_G - x)}{(1 - x)(x_G - x_F)} S_F \quad (4)$$

The factor multiplying S_G (S_F) in equation (4) is the number of labeled molecules in phase G (F) divided by the total number of labeled molecules in the sample. Under some circumstances, it may be necessary to apply a correction to account for different transverse relaxation rates in the coexisting phases.

Consider two spectra, $S(x_A)$ and $S(x_B)$, obtained for sample compositions x_A and x_B on the same tie line within a two-phase region. They should consist of the same pair of endpoint spectra superimposed in differing proportions. If $x_A > x_B$, then $S(x_A)$ will contain a higher proportion of S_G than will $S(x_B)$. By subtracting one observed spectrum from the other, one can obtain a spectrum that is exclusively characteristic of one or the other endpoints. K is defined as the fraction of $S(x_B)$ that must be subtracted from $S(x_A)$ to yield S_G . Similarly, K' is the fraction of $S(x_A)$ that must be subtracted from $S(x_B)$ to yield S_F . The endpoint compositions are given by

$$x_G = \frac{x_A(1 - x_B) - Kx_B(1 - x_A)}{(1 - x_B) - K(1 - x_A)} \quad (5)$$

and

$$x_F = \frac{x_B(1 - x_A) - K'y_A(1 - x_B)}{(1 - x_A) - K'(1 - x_B)} \quad (6)$$

For locating phase boundaries, spectral subtraction complements other methods in which properties are observed as sample temperatures are scanned through the region of interest. If several spectra are available along a tie line, a consistent result obtained from a series of different pairwise subtractions provides evidence that the system obeys the lever rule and that the observed spectral changes do indeed reflect two-phase coexistence. Scanning techniques such as DSC depend on the

identification of a threshold temperature at which a property, such as excess heat capacity, exhibits departures from baseline behavior. As such, they are sensitive to the way in which the baseline is extrapolated into the coexistence temperature range. It is significant that the spectral difference approach is based on equilibrium partitioning of the sample.

In practice, K or K' is varied until features characteristic of one or the other coexisting phases are eliminated. The ease with which the appropriate values of K and K' are assigned is very sensitive to the distinctness of the spectra corresponding to the two endpoints. The DPPC- d_{62} -cholesterol system presented a particular challenge to the spectral subtraction technique. Figure 2 shows the form of the phase diagram obtained by Vist and Davis.¹⁸ The labels *ld* and *so* correspond to the liquid-disordered (or liquid crystal) and solid-ordered (or gel) phases, respectively. The *ld*-*so* coexistence region below 7.5 mol% cholesterol was less than 1 °C wide. The nearly horizontal boundaries of this region were determined by inspection of spectra for samples with cholesterol concentration below 7.5 mol% under the assumption that spectral subtraction in this region would be overly sensitive to uncertainty in the sample temperature. Figures 1(a) and 1(d) are characteristic of the *ld* and *so* spectra above and below this two-phase region. The spectra in the *lo* phase beyond about 20 mol%, which Vist and Davis¹⁸ labeled the ' β ' phase, are axially symmetric but with a greater

Figure 2 A schematic drawing of the PC-cholesterol phase diagrams. For DPPC- d_{62} , the three-phase line (separating *so* + *lo* from *ld* + *lo*) is at 37 °C and extends from about 7 mol% to 20 mol% cholesterol.¹⁸ For POPC- d_{31} -cholesterol, the three-phase line is at about -7 °C and extends from 7 mol% to about 20 mol% cholesterol.⁴⁵ For stearoyl-elaidoyl-PC- d_{35} -cholesterol, the three-phase line is at about 31 °C and extends from about 10 to 25 mol% cholesterol.⁴⁶ *ld* is the liquid-disordered phase (also called liquid crystal or L_α). *lo* is the liquid-ordered phase (called β by Vist and Davis¹⁸), *so* is the solid-ordered phase (also called gel or L_β). (Adapted from Vist and Davis¹⁸)

average splitting than in the liquid crystalline phase. Figures 1(c) and 1(f) are characteristic of this phase. Within the *ld*-*lo* coexistence region, there was evidence that fast exchange between domains of the two phases caused averaging of the spectra, and spectral differences again were not used. The boundary between *ld* and the *ld*-*lo* coexistence region was determined from DSC studies. Figure 1(b) corresponds to a point inside the two-phase region close to the boundary. Below 20 mol% cholesterol, the lower boundary of this region is a three-phase line at which the *so* phase melts into the *ld* phase. This line was primarily identified from a sharp transition observed calorimetrically. The boundary between the *ld*-*lo* coexistence region and the *lo* region was assigned at the point where the sharp doublets of the *lo* phase broadened as the sample temperature was increased. This was taken to indicate the onset of spectral averaging due to fast exchange with domains of liquid crystal. Determining the exact location of this boundary remains somewhat problematic.

Within the *so*-*lo* region, spectral subtraction provided important evidence of predominantly vertical boundaries. Figure 1(e) is characteristic of spectra in this region. Such spectra are not obvious superpositions of spectra from two coexisting phases. However, spectral subtraction did give rise to endpoints that were characteristic of the *so* phase and axially symmetric endpoint spectra with large quadrupole splittings that were identified as arising from the *lo* phase. That these were indeed true endpoint spectra was confirmed by comparison with spectra obtained from samples having cholesterol concentrations close to the endpoint concentrations determined by spectral subtraction.

The doublet with the smallest splitting in the axially symmetric spectra arises from the methyl deuterons at the ends of the acyl chains. At high cholesterol concentration, the methyl doublet was split, indicating a slight difference in ordering of the two chains near the bilayer center (see Figure 1).¹⁸ The temperature dependence of the splitting was examined,⁴⁴ and a correspondence was noted between the temperature at which the inequivalence of the methyl deuterons disappears and the boundary of the *ld*-*lo* coexistence region reported by Vist and Davis.¹⁸ Partial orientation of DPPC- d_{62} vesicles containing 25 mol% cholesterol was found between 36 and 42 °C, which was attributed to a change in the mechanical properties of the bilayer. The temperature dependence of these effects in the *lo* phase may reflect a reorganization of cholesterol from a position near the bilayer center to one closer to the headgroup region with increasing temperature.

Spectral differences were also used to determine the phase diagrams of mixtures of cholesterol with two unsaturated PCs.⁴⁵ Although the phase diagrams were shifted to lower temperatures, in accordance with the T_m values of the phospholipids, remarkable similarities with the DPPC-cholesterol phase diagrams are apparent. A universal shape for the PC-cholesterol phase diagram was postulated, and it was suggested that the β or *lo* phase is probably common to cholesterol-rich biological membranes. No attempt was made to define the *ld*-*lo* coexistence region. Recently, the comparison was extended to mixtures of stearoyl-elaidoyl-PC and cholesterol, which were also found to resemble the DPPC-cholesterol phase diagram.⁴⁶ In each binary mixture, the shift on temperature of the three-phase line, relative to that for DPPC-cholesterol, is approximately the same as the shift in the pure phospholipid transition temperature relative to

that for DPPC. Theoretical efforts to model the DPPC phase diagram have been reviewed.^{47,48}

4 OTHER RECENT PHOSPHOLIPID-CHOLESTEROL PHASE DIAGRAM STUDIES

The determination of phospholipid-cholesterol phase diagrams by using neutron scattering has been reviewed.⁴⁹ Electron spin resonance studies generated phospholipid-cholesterol phase diagrams in which a phase boundary was detected that appears to correspond to the boundary between the *ld-lo* coexistence region and the *lo* region beyond 20 mol% cholesterol.⁵⁰

The phospholipid-cholesterol phase diagram has also been studied by Griffin and co-workers using a variety of techniques, including ¹³C NMR. A region of two-phase coexistence below *T_m* was found in the phase diagram for dipalmitoylphosphatidylethanolamine-cholesterol mixtures by using ²H and ¹³C NMR.⁴² In a similar study with distearoyl-PC (DSPC)-cholesterol and DPPC-cholesterol systems, the ¹³C NMR spectrum of the *sn*-2 carbonyl was found to be an axially symmetric powder pattern with a width of about 100 ppm in the gel phase.^{42,51} In the liquid crystalline phase, the spectrum is a narrow line (5–10 ppm in width), suggestive of isotropic motion. This behavior is attributed to a conformational change in which the unique axis of the chemical shift tensor orients close to the magic angle. In the *P_β'* phase, a superposition of the powder pattern and narrow line spectra is seen. As cholesterol is added, the temperature at which the narrow component first appears is lowered. Where the narrow and powder pattern components are superimposed, the narrow component is broadened. The presence of the narrow and powder pattern spectral components together was taken to indicate the coexistence of a cholesterol-rich phase (*LG₁* or *lo*) and the gel phase (*L_β* or *so*). The broadening of the narrow component was simulated by assuming exchange between domains of the two phases. In this way, estimates of domain size have been obtained. The boundary of the *LG₁* or *lo* region above the temperature of the three-phase line was determined by ²H NMR. The boundary of the *lo* region below the temperature of the three-phase line was found to be shifted to higher cholesterol concentration in mixtures containing the longer chain DSPC compared with DPPC.

The boundary of the DPPC-cholesterol *so-lo* region determined by ²H NMR appears to be rather different from that determined by ¹³C NMR. Carbon-13 NMR measurements indicated that the boundaries of this region curve toward higher cholesterol concentration as the temperature is lowered,⁵¹ whereas ²H NMR measurements showed the corresponding boundaries to be nearly vertical.¹⁸ Similar results were obtained in mixtures of cholesterol with some unsaturated phospholipids.^{45,46} However, the temperature ranges over which these boundaries have been determined by ²H NMR are limited.⁵¹ Whether there is really a discrepancy between the findings of the two techniques regarding these boundaries is not clear at this time.

A variety of techniques, including ²H NMR, electron spin resonance, and fluorescence recovery after photobleaching, have been applied to the construction of phospholipid-cholesterol phase diagrams⁵² that are qualitatively similar to the one reported by Vist and Davis.¹⁸ Based

on ²H NMR studies of bilayer thickness in a series of PCs with increasing chain length, it was suggested that cholesterol spans the bilayer in the *ld* phase and that, with increasing cholesterol concentration and increasing order, the bilayer becomes partially interdigitated in the *lo* phase.⁵³ The fluid phase immiscibility represented by the *ld-lo* region was attributed to this behavior.

5 CONCLUDING REMARKS

What are the implications of these findings for biological membranes? There are common features for each of the lipid-cholesterol phase diagrams, with three phases, *so*, *lo*, and *ld*, plus the corresponding two-phase regions appearing for each phospholipid-cholesterol combination. The phase boundaries show similar, although not identical, properties with respect to cholesterol concentration, with their positions being dependent on the specific phospholipid involved.

At their physiological temperature(s), the lipids of most membranes will be above *T_m* and above the three phase lines in the phase diagrams. Plasma membranes, therefore, will be in the *lo* or, at elevated temperatures, in the *ld* state. Under equilibrium conditions, these are continuous phases, although interaction energies might vary between cholesterol and individual, specific phospholipids. (Indeed, such comparisons should be made with full knowledge of the phase diagrams, so that cholesterol-phospholipid interactions in comparable phases can be compared.) Subcellular membranes and other membranes having low cholesterol content, on the other hand, while possibly being in the phases just mentioned, might also exist in the *ld-lo* two-phase region above the three-phase line. Thus, cholesterol-enriched and cholesterol-poor regions could coexist in membranes, and these domains might have important consequences for insertion and regionalization of proteins, and for modulation of protein functions.

1 INTRODUCTION

A variety of polysaccharides are known to play essential roles as the structural components in the cell walls of plant and microorganisms, in insect cuticles, as storage polysaccharides, as matrix components in animal fluids and connective tissues, and as molecular signals for biological recognition. These functions are strongly related to their respective secondary structures, taking in the solid, gel, or solution states. Nevertheless, it is not easy to reveal the secondary structures of these polysaccharides either in the solid or in solution, as compared with those of globular proteins or nucleic acids which have been extensively studied by X-ray diffraction or multidimensional NMR spectroscopy. This is mainly because the crystallization of polysaccharides for an X-ray diffraction study is extremely difficult and the number of interresidual nuclear Overhauser enhancements in solution NMR is not sufficient for the purpose of model building. Moreover, it should be emphasized that the secondary structures of polysaccharides are generally very heterogeneous, especially in the gel state in which several different kinds of domain are simultaneously present.

Conformational elucidation by solid state NMR spectroscopy as a means for in situ structural analysis is especially important for a number of polysaccharides, because they are in many instances not soluble in mild solvent systems (such as aqueous solution) and other spectroscopic means for this purpose are virtually unavailable. It should be anticipated that solubilization in either alkaline or DMSO solution can usually be associated with a conformational change. In addition, too much reliance should not be laid on a secondary structure as deduced by fiber X-ray diffraction studies, because any physical treatment to improve the crystallinity (such as thermal treatment) may cause a conformational change. There remains an ambiguity about secondary structure owing to the limited number of diffraction data available. In this respect solid state NMR is invaluable as a complement to fiber X-ray diffraction as well as a means to gain insight into the dynamic aspects of polysaccharides, especially in relation to a study of gel networks.

2 CONFORMATION-DEPENDENT ^{13}C CHEMICAL SHIFTS

We have previously shown that the ^{13}C chemical shifts of a variety of molecular systems, including polypeptides and proteins, carbohydrates and polysaccharides, ionophores, etc., vary by as much as 8 ppm depending on their conformations.^{1,2} In principle, such a conformation-dependent change in polysaccharides is observable either in the solid state or in solution when rapid conformational isomerism about the glycosidic linkages is frozen. However, there are a limited number of examples which exhibit the existence of conformation-dependent ^{13}C chemical shifts: ^{13}C chemical shifts recorded in solution are generally identical, within experimental error, to those observed in the solid state, as in higher molecular weight $(1 \rightarrow 3)\text{-}\beta\text{-D-glucans}$ and $\alpha\text{-cycloamylose}$. The situation arose when rapid rotational motion about the glycosidic linkages was frozen (even in solution) due to the formation of cross-links or to the presence of cyclic structures for the $(1 \rightarrow 3)\text{-}\beta\text{-D-glucans}$ and $\alpha\text{-cycloamylose}$, respectively.

The existence of conformation-dependent ^{13}C chemical shifts, however, is more clearly visualized by an examination of the ^{13}C chemical shifts of solid polysaccharides which have a variety of polymorphs. It is also useful to examine the ^{13}C NMR spectra of crystalline cycloamyloses enclosing a variety of guest molecules, because detailed conformational data for such complexes are available from single crystal X-ray diffraction studies. We previously demonstrated that the C-1 and C-4 ^{13}C chemical shifts of crystalline cycloamyloses enclosing various types of guest molecules could be well related to a set of torsion angles about the glycosidic linkages (ϕ , ψ).³ Later, similar but slightly different relationships^{4,5} were proposed. Therefore, conformational elucidation by means of solid state NMR is feasible on the basis of the concept of conformation-dependent ^{13}C chemical shifts.^{1,2}

3 SECONDARY STRUCTURE OF GEL-FORMING POLYSACCHARIDES

It is well recognized that cross-links of polysaccharide gels are formed via several degrees of molecular association of the ordered polysaccharide chains. It is thus important to obtain the detailed in situ secondary structure of various polymorphs of polysaccharides by solid state NMR as reference data useful for conformational studies of gel samples.

3.1 $(1 \rightarrow 3)\text{-}\beta\text{-D-Glucans}$

As an illustrative example, we first demonstrate comparative ^{13}C NMR studies on linear and branched $(1 \rightarrow 3)\text{-}\beta\text{-D-glucans}$ isolated from bacteria and reserve polysaccharide, and fungi (edible mushrooms), respectively.^{6,7} Curdlan [(1), Figure 1], a bacterial linear $(1 \rightarrow 3)\text{-}\beta\text{-D-glucan}$ from *Alcaligenes faecalis* (Wako Pure Chemicals, Osaka, Japan) is able to form a firm elastic gel when its aqueous suspension is heated at a temperature above 54 °C. On the other hand, several branched glucans such as lentinan (Ajinomoto Co. Japan), schizophyllan (Taito, Japan), etc. (2) from various types of mushrooms are able to form gels of a rather brittle type at higher

Figure 1 Primary structures of a variety of polysaccharides

concentrations (>10%). Such a difference in macroscopic texture of these gel samples is closely related to a different architecture of the network structure between the two types of gels, as will be discussed later in more detail. In fact, rather sharp ^{13}C NMR signals (about 40% of the total NMR spectrum) are visible from curdlan gel using conventional liquid state NMR with broadband decoupling.⁸ The C-1 and C-3 ^{13}C chemical shifts from the elastic gel were displaced to high frequency by 2.8 and 3.2 ppm, respectively, as compared with those of a lower molecular weight glucan with a random coil conformation. As pointed out in the previous section, such a conformation-dependent ^{13}C chemical shift of (1 → 3)-β-D-glucans arises from the fact that the rotational motions of the polysaccharide backbone about the glycosidic linkages are frozen due to the formation of an ordered helical conformation. The polysaccharide chain in this case must be a *single* helical species in spite of the existence of a triple helical model, based on fiber X-ray diffraction studies,^{9,10} because the molecular chain is found to be rather flexible, as demonstrated by relaxation parameters such as the spin–lattice relaxation times and the NOE.⁶ In contrast, all of the ^{13}C NMR signals of the branched glucans were found to be completely suppressed in the gel state as recorded on a traditional solution state NMR spectrometer.¹¹ This finding implies that the molecular conformations of these two types of polysaccharides are different from each other. It is essential for this reason to examine the solid state ^{13}C NMR spectra of various types of polymorphs in (1 → 3)-β-D-glucans for use as reference data.

Figure 2 illustrates the ^{13}C NMR spectrum of a hydrated sample of curdlan (b) obtained by placing it in a desiccator at 96% relative humidity for 8 h compared with that of the anhydrous powder as received from the manufacturer (a)¹² and annealed curdlan¹³ prepared by heating an aqueous suspension at 150 °C followed by slow cooling (c). It is noteworthy

Figure 2 ^{13}C CP MAS NMR spectra of curdlan in the solid state: (a) anhydrous; (b) hydrated; and (c) annealed¹²

that the ^{13}C NMR linewidths of the hydrated sample are considerably narrowed in comparison to those of the anhydrous sample and are comparable to those of the annealed curdlan [Figure 2(c)]. The C-3 ^{13}C chemical shift of curdlan hydrate is displaced to low frequency by 2.5 ppm with respect to that of the anhydrous state. Distinction between the hydrated and annealed curdlan is straightforward by means of the C-5 chemical shifts (75.8 ppm and 77.5 ppm for the former and latter, respectively) and the peak separation between the C-5 and C-2 signals (2.0 and 3.2 ppm, respectively). Lyophilized curdlan from DMSO solution gave rise to narrower spectra but the peak positions were exactly the same as those for the anhydrous sample.¹⁴ Annealed curdlan may be related straightforwardly to the triple-helix form on the basis of its powder X-ray diffraction by reference to previous fiber diffraction data.^{9,10}

Hydrated curdlan gave rise to ^{13}C NMR signals which were identical to those observed in the gel state. Hence, this form was ascribed to the flexible single helix already mentioned. Consistent with this view, a recent fiber X-ray diffraction¹⁵ study showed the presence of a 6/1 single helix conformation for the curdlan gel prepared by heating an aqueous suspension at 70 °C for 10 min, although Fulton and Atkins previously ascribed a similar diffraction pattern to a 7/1 triple helix conformation.¹⁶ It is surprising that the C-1 and C-3 chemical shifts of the single helical curdlan hydrate are very similar to those of the triple helical annealed curdlan, although distinction between the two forms is possible from the C-2 and C-5 peaks. This is because the two pairs of the torsion angles about the glycosidic linkages (ϕ , ψ) are very similar, as revealed by X-ray diffraction studies.^{10,15} The anhydrous form, on the other hand, is ascribed to a single-chain form whose torsion angles vary to some extent from those of the single helix form owing to loss of hydrated water molecules (which are essential for stability in the single helix conformation). In a similar manner, DMSO molecules in the single-chain form are complexed with the polysaccharide chains (ca. 0.5 DMSO molecules per residue)¹⁴ and may play an important role for the conformational stabilization, although they are readily replaced by water molecules on hydration

to yield the single helix form.^{12,14} This situation is very similar to the case of DMSO molecules complexed with V-amylose, which are very easily replaced by water molecules by hydration, leading to the conversion to the B- form, as will be described later.

Linear (1 → 3)- β -D-glucans of low molecular weight oligomers such as laminariheptaose and acid-degraded curdlan with a degree of polymerisation (*DP*) of 14 can adopt neither the single helix nor triple helix form, as judged from the characteristic ¹³C signals.^{12,13,17} Interestingly, glucans of either short-chain (*DP* < 14) or longer-chain species are incapable of forming triple helices by lyophilization from aqueous solution. Laminaran from *Laminaria* species (*DP* 39) turned out to be able to exist in the triple helix form by lyophilization from aqueous solution, although this polysaccharide adopts a random coil form in aqueous solution.¹³ In contrast, triple helix conformations were achieved when high molecular weight branched (1 → 3)- β -D-glucans such as schizophyllan or HA- β -glucan were lyophilized from their aqueous solution, although the single-chain form was available from an aqueous solution of lentinan.¹⁷ It is now clear that the obvious preponderance of the single helix conformation for the linear (1 → 3)- β -D-glucans of high molecular weight arises mainly from insufficient hydration. Once this molecule is completely dissolved in an aqueous solution at a temperature above 150 °C, it is able to refold to yield the triple helical conformation when cooled slowly to ambient temperature.¹³ It is thus expected that such a conversion is inefficient when heated samples are cooled rapidly (at most 50%).¹³ It is noteworthy that conversion of the single helix to the triple helix by annealing at 150 °C is accompanied by fragmentation of the polymer chain due to thermal degradation from an initial *DP* of 3930 to a final *DP* of 110.¹⁸ Such an annealing is not necessary in the case of the branched glucans, because these molecules are well hydrated in aqueous media at ambient temperature. It appears that rather weak intermolecular association of the branched glucan (as compared with that of the linear glucan) arises from the presence of a pendant glucose moiety (Figure 1) for every two or three glucose residues. This is the reason why the branched (1 → 3)- β -D-glucans and laminaran have a preponderance of the triple helix over the single helix conformations.

In general, several types of polysaccharides including (1 → 3)- β -D-glucans can acquire the double or triple stranded form as the most energetically stable, as expected from a molecular mechanics calculation.¹⁹ Nevertheless, any given polysaccharide sample does not always take the energetically most stable conformation, because of different sample histories. Distinction between the single and multiple helical chains, however, is not always straightforward to obtain by X-ray diffraction, because distinguishing multiple stranded coaxial helices and nested single helices is one of the most difficult problems encountered in interpreting fiber diffraction data.²⁰ It should be emphasized that this problem is readily solved by examination of the conversion diagram of these polysaccharides after a series of physical treatments, as summarized in Figure 3. The present approach can be further extended to any types of polysaccharide. In fact, a very similar conversion diagram was recently obtained for (1 → 3)- β -D-xylan (3), which is also found to acquire the three above-mentioned types of conformation, as may be expected from its structural similarity with (1 → 3)- β -D-glucans.²¹ The

Figure 3 Conversion diagram for (1 → 3)- β -D-glucans by various physical treatments (based on Saitô et al.^{12,13})

triple helical conformation was initially proposed for (1 → 3)- β -D-xylan²² and then adopted for (1 → 3)- β -D-glucan, because the C-6 hydroxymethyl group of the latter is located outside the helical chains. It turned out that the triple helix conformation of the former is more stable than that of the latter because of the greater hydrophobic character in the polymer chain and it cannot be readily converted to the single chain form even if dissolved in DMSO. This type of conversion was made possible by dissolution of the sample in aqueous zinc chloride solution in place of the more common DMSO solution.²¹

3.2 Amylose and Starch

Amylose (4) has a common feature with (1 → 3)- β -D-glucans as viewed from the presence of the single helical conformation, which is stabilized by DMSO molecules, and also from its gel-forming ability. Amylose and starch are known to have the following four kinds of polymorphs: V-, A-, B-, and C-forms.^{23,24} The V form exists as a complex with a variety of small organic molecules and has a left-handed single helical conformation. The A- and B-forms are found in cereal and tuber starches, respectively, and can be distinguished by the splittings of the C-1 peaks as triplet and doublet peaks, respectively.^{25–27} In contrast, V-amylose gives rise to single lines.²⁸ The C-4 peak of V-amylose is particularly displaced to high frequency by ca. 4–5 ppm from that of the B form. These amylose polymorphs can also be mutually interconverted by a series of physical treatments in a similar manner to (1 → 3)- β -D-glucan, as demonstrated for amylose of low molecular weight (*DP* 17, Figure 4).²⁹ Obviously, anhydrous amylose lyophilized from a DMSO solution [Figure 4(b)] gave rise to a spectral pattern of the V form. The anhydrous powder as received, however, has an amorphous structure distorted from the B form, as judged from the broad envelope of the ¹³C NMR signal in the C-1 region and the absence of the C-4 peak at 81 ppm [Figure 4(a)]. Furthermore, hydration of the anhydrous powder or V-amylose resulted in conversion to the B-amylose as judged from the ¹³C NMR spectra [Figure 4(c)]. It is interesting that such conversion occurs efficiently for amylose of either low (*DP* 17) or high (*DP* 1000) molecular weight but was incomplete for amylose of intermediate molecular weight (*DP* 100).²⁹

The secondary structure of the B form was initially considered to be the single helical conformation,³⁰ since the conversion of the V- to the B-form amylose takes place on humidification.³¹ Later, however, the structure was refined as

Figure 4 ^{13}C CP MAS NMR spectra of low molecular weight amylose (DP 17): (a) anhydrous powder; (b) anhydrous lyophilized sample from DMSO solution; (c) hydrated amylose powder; and (d) hydrated iodine complex²⁹

a right-handed double helix in an antiparallel fashion.³² The handedness of the double helix form, however, was recently revised as a left-handed double helix.³³ Nevertheless, it is hardly likely that simple humidification of amylose by placing it in a desiccator at a relative humidity of 96% causes such a drastic conformational change. In this connection, it is crucially important to clarify whether the secondary structure of B-amylose is a left-handed single helix as suggested from solid state NMR or a left-handed double helix as suggested from fiber X-ray diffraction study.

It was expected that ^2H NMR spectra of $^2\text{H}_2\text{O}$ or $\text{DMSO-}d_6$ complexed to amylose by forming the B- or V-form would be split into a doublet pattern, with the separation of peaks being about 100–200 kHz and 40 kHz (with C_3 rotation of the methyl group), respectively, if they are tightly bound to the polymer chains (static). It emerged, however, that only a singlet was visible as a result of rapid isotropic averaging of the quadrupole interaction in the solid state, with correlation times on the order of 10^{-6} s. The correlation times of isotropic tumbling of $^2\text{H}_2\text{O}$ and $\text{DMSO-}d_6$ as estimated from ^2H spin–lattice relaxation times are found to be in the vicinity of the T_1 minimum and on the high-temperature side of the T_1 minimum, respectively.²⁹

4 DYNAMIC ASPECTS OF POLYSACCHARIDE GELS

Network structures of gel samples should be highly heterogeneous from the conformational and dynamic point of

view. Any single NMR measurement, however, does not give rise to such information, because the correlation times of the molecular motions may be broadly distributed from the liquid- to solid-like domains. We have already demonstrated that ^{13}C NMR signals from the liquid-like domains are easily visible with a conventional solution state spectrometer but those of the solid-like domains are not.^{5,6} It is therefore necessary to record NMR signals from these solid-like domains in order to gain some insight into the gel structure and dynamics. It is accordingly a major advantage of the NMR approach that it is able to select a particular domain from a variety of motionally different domains.

We have recorded ^{13}C NMR spectra of curdlan gels (Figure 5) by various methods including broadband decoupling for the liquid-like domain as discussed above (b), high-power dipolar decoupling with magic angle spinning (MAS) for intermediate domains between the liquid- and solid-like domains (c), and cross-polarization magic angle spinning (CP MAS) for the solid-like domains (d), and have compared these with the ^{13}C NMR spectrum of hydrated curdlan (a).³⁴ Such comparison indicated that the single helix form is dominant for all of the motionally different domains of an elastic curdlan gel, although a low intensity peak arising from the contribution from the triple helix is visible in the solid-like domains as shown by the arrowed peak in the CP MAS NMR spectrum. It is worthwhile to relate here the present view of the gel structure with the data for gel strength as a function of heating temperature:³⁵ the gel strength is almost the same at temperatures between 60–80 °C (low-set gel) and thereafter increases with heating temperature together with the development of turbidity and shrinkage of the gel (high-set gel). The first step of gelation thus corresponds to the formation of pseudo cross-links by hydrophobic association of

Figure 5 ^{13}C NMR spectra of curdlan gel (b–d) and curdlan hydrate (a) recorded by various types of NMR measurements: (a) and (d) by CP MAS; (b) by broadband decoupling; and (c) by MAS experiments³⁴

the single helical chain. The increased gel strength in the high-set gel is well explained in terms of an increased proportion of the triple helical conformation.^{5,6}

On the other hand, we found that ¹³C NMR spectra of branched glucans such as lentinan, schizophyllan, and HA-β-glucan exhibited characteristic peaks of the triple helix conformation.³⁴ As pointed out, such a preponderance of the triple helix forms resulted in the complete absence of the peaks from the liquid-like domains.^{5,6} In this connection, Yanaki and co-workers³⁶ showed that the triple helical chain of (1 → 3)-β-D-glucans is stiffer than that of native collagen, as manifested from the measurements of persistent chain length for schizophyllan (2000 ± 300 Å). This means that the resulting slow tumbling motion of the stiff rod-like triple helices is not sufficient to average out the dipolar or chemical shift anisotropy interactions in the gel state. Thus, it follows that the major gelation mechanism for the branched (1 → 3)-β-D-glucans proceeds from partial association of the triple helical chains. It appears that the absence of the flexible molecular chain is consistent with the property of a brittle gel. Here we point out that the linear and branched (1 → 3)-β-D-glucans so far discussed are involved in a variety of host-defence biological responses such as antitumor activity, activation of the coagulation system of horseshoe crab amebocyte lysate (LAL), etc. It is interesting that such biological response is initiated by recognition of the molecular chains of the single helical conformations.^{18,37,38}

Gidley³⁹ showed that amylose gel exhibits two kinds of ¹³C NMR signals: B type signals from motionally restricted regions as recorded by the CP MAS technique and signals identical to those found in aqueous solution. Obviously the latter signals can be ascribed to the presence of a mobile region (liquid-like domain) in the network whose conformation is random coil. The former peaks are naturally ascribed to the solid-like domain with cross-links, either consisting of double helical junction zones,³⁹ or aggregated regions of the single helical chains²⁹ as discussed in the previous section. To date, two different views have been presented for the gelation mechanism of amylose: Miles et al.⁴⁰ have suggested that gels are formed upon cooling molecularly entangled solutions as a result of phase separation of the polymer-rich phase, whereas Wu and Sarko³³ proposed that gelation occurs through cross-linking by double helical junction zones. Recently, we measured the ¹³C spin-lattice relaxation times of the liquid- and solid-like domains of starch gel by means of dipolar decoupled single pulse MAS and CP MAS, respectively.⁴¹ It turned out that the *T*₁ of the C-6 carbon is 0.16 s and 2.1 s for the former and latter, respectively. It appears that such a long *T*₁ for the latter as compared with that of other types of swollen gels (<0.5 s) arises mainly from motionally restricted crystalline portions consisting of aggregated molecular species such as single helical chains. In any case, it is crucially important to distinguish single helical chains from double helical chains by means of solid state NMR spectroscopy.

5 CONCLUDING REMARKS

It has been demonstrated that the solid state NMR approach is a very powerful means of clarifying conformational features of a variety of polysaccharides in an empirical manner based on the concept of the conformation-dependent displacements

of ¹³C chemical shifts. Careful examination of an NMR-based conversion diagram by a series of physical treatments has proved to be a very useful means for the distinction of single-chain/multiple helices. The application of a modern methodology is urgently required to determine the secondary structure in a nonempirical manner, such as rotational echo double resonance or rotational resonance as currently being applied to a variety of peptides or proteins in the solid state.

1 INTRODUCTION

There are strong motivations for pursuing solid state NMR of protons, namely the inherently good sensitivity and the possibilities for study of hydrogen bonding via chemical shifts. Despite its enormous potential, solid state NMR of protons in biomolecules has had surprisingly few applications in comparison with other high-resolution NMR methods for studying biological macromolecules. In this article we discuss experimental solutions to the problem of spectral resolution and the analysis of spectra for chemical information. Although essentially all of the successful measurements of chemical shift and shift anisotropy were obtained on simple crystalline solids we also discuss possible future applications in structural biology.

2 APPROACHES TO NARROWING PROTON RESONANCES

Producing narrow proton linewidths is the most significant challenge to solid state proton NMR. For the case of a typical rigid organic solid, ^1H NMR spectra obtained without sample spinning or with moderate speed sample spinning show very broad lines, on the order of a few tens of kilohertz. Narrowing of these lines by the technique of combined rotation and multiple pulse spectroscopy, CRAMPS,^{1–4} or by dilution of the protons^{5–7} has been demonstrated in crystalline small molecules. These methods have provided the means to study hydrogen bonding and proton exchange in solids, but practically no high-resolution solid state ^1H NMR applications

to macromolecules have been reported. In contrast to rigid organic solids, solids with high molecular mobility such as lipids and membrane structures often provide well-resolved ^1H NMR simply by Bloch decay acquisition with slow magic angle spinning.^{8–11}

The CRAMPS method is the most common experimental approach to achieving high-resolution ^1H spectra of materials in the solid state. It has been used in interesting applications of chemical analysis,^{12–15} and probably has the most potential for general studies of amorphous biological solids. Proton NMR linewidths obtained by CRAMPS or magnetic dilution can be as low as 0.2 ppm, which could be sufficient to separate the typical functional groups found in a protein but of course would never be adequate for site-specific assignments of even a small peptide. Highly crystalline compounds typically produce the narrowest lines, while compounds with some amorphous character produce somewhat broader lines.¹⁴ Macroscopic susceptibility due to the shape of the microcrystal presumably contributes to the linewidth, and specific anisotropic bulk susceptibility effects in aromatic systems have been discussed.¹⁴

An alternative method that has been little pursued to date is the detection of deuterons during magic angle spinning (MAS). With this approach resolution comparable to that of CRAMPS or dilution can often be obtained without special effort,^{16,17} and spectral overlap can be avoided by utilizing selective labeling. Considerable spectral intensity is squandered into spinning sidebands, so application of methods to fold the sidebands together is important. On the other hand, the quadrupolar constants and dynamic information normally obtained from static ^2H NMR can be derived from the sideband patterns in these spectra. Several reports of cross polarization between deuterium and protons have appeared.^{16,18}

In the following discussion we will focus more on CRAMPS than the other two approaches because of the much larger existing literature and the far fewer complications with sample preparation. We illustrate the typical appearance of CRAMPS spectra of simple organic biological solids with a series of CRAMPS spectra of amino acids and dipeptides in Figure 1; some of these samples have also been characterized by measurement of dilute protons⁶ or by spinning ^2H spectra.¹⁷ It is apparent from Figure 1 that the linewidths are significantly below 1 ppm in every case and the spectra allow resolution

Figure 1 The 200 MHz BR-24 spectra of crystalline amino acids (as indicated). Pulse length was $1.3\ \mu\text{s}$ with a τ value of $2.3\text{--}3.0\ \mu\text{s}$ and spinning speeds of $1.0\text{--}1.5\ \text{kHz}$. Sixteen transients were accumulated. Glu = glutamic acid, Asp = aspartic acid, Ala = alanine, Arg = arginine, Lys = lysine, Gly = glycine

Figure 2 Typical CRAMPS spectra of biological molecules, measured at 187 MHz with the BR-24 pulse sequence.¹⁹ Top: amylopectin; middle: γ -globulin; bottom: coconut oil. Spectra were acquired with MAS spinning speed of 1–2 kHz, pulse width = 1.0–1.2 μ s, τ = 3.0 μ s, repetition time 1.7 s

of one chemical classification from another. For aliphatic or aromatic protons the chemical shifts are comparable to those known from solution state experiments, that is –1 to 2 ppm for methyl groups, 1–3 ppm for methylene, 3–5 ppm for methine, and 6–8 ppm for aromatic protons. Unlike solution spectroscopy, in solid state experiments observing acid and other exchangeable protons is possible, and in particular for the case of carboxylic acids the range in typical shifts is quite a lot broader than the linewidths. The amine and many of the other N–H functionalities are often around 7–8 ppm, while imidazole protons and structural water protons and carboxylic acids can be found at a broad range of shift values depending on hydrogen bonding, with strongly hydrogen-bonded groups being significantly deshielded (10–20 ppm). The chemical shifts and lineshapes for resonances in hydrogen bonding groups are discussed in detail in the following sections.

Typical ^1H CRAMPS spectra of other biological materials are also exhibited in Figure 2.¹⁹ The carbohydrate spectrum (top) is dominated by methine and hydroxyl protons. The protein spectrum (middle) shows contributions from methyl, methylene, methine, amine, and other groups but is largely unresolved. A methylene resonance at 1.3 ppm dominates the lipid spectrum (bottom). As noted above, MAS-only spectra of lipids provide good ^1H resolution. Proton linewidths of lipids and highly mobile materials are often narrower in MAS-only spectra than in CRAMPS spectra¹⁹ due to pulse imperfections in the multiple pulse sequence.

3 INFORMATION FROM THE LINESHAPE

All three detection methods show certain potentially confusing effects that deserve special comment. As has been reported previously^{1,20} dynamic processes can interfere with the CRAMPS detection of groups undergoing motion if the correlation times are comparable to the pulse width, the multiple pulse cycle time, or to the sample spinning speed. This effect is often seen at room temperature in the form of missing amine resonances. Amine groups enact a three-site hopping motion on the microsecond timescale near room temperature since they have activated barriers in the range of 30 kJ mol^{–1}. This motion has been previously characterized by wide-line ^1H T_1 measurements²¹ but not by lineshape methods. Such amine lines that are broad or undetected near room temperature

Figure 3 The 200 MHz BR-24 spectrum of L-aspartic acid at various temperatures. Note that the amine resonance at 7.7 ppm disappears near room temperature (RT) due to the microsecond correlation time for the amine's threefold hopping rate. This behavior is quite common for amine groups although the critical temperature is variable

are readily detected at temperatures above 70 °C or below –100 °C in typical cases. Figure 3 shows variable temperature ^1H CRAMPS spectra of L-aspartic acid in which the amine line at 7.7 ppm illustrates this effect. Other effects on the lineshapes as a function of temperature are often observed, and analysis of these lineshapes by explicit simulation would be informative but has not yet been accomplished. Other than the amine rotation, common local motions in proteins rarely result in loss of signal because the rates are not on the microsecond timescale near room temperature. The ^2H MAS spectra exhibit lineshape and intensity effects for amines in a comparable temperature range: here the sampling rate of data collection is usually in the submegahertz range so again motions in the microsecond range interfere with detection. Proton spectra of magnetically diluted (deuterated) samples detected using Bloch decay during MAS would presumably show lineshape effects due to much slower motions, approximately on the millisecond timescale. Hence detection of sharp spectra due to the amine peaks is usually straightforward by ^1H MAS spectra. In all three methods interpretation of line intensities is quite unreliable because of all of these lineshape effects and/or the uncertainties involved in the extent of chemical incorporation of deuterium.

Protons that are directly bound to nitrogens often exhibit a lineshape that is obviously affected by the incomplete averaging of dipolar coupling to the ^{14}N resulting from the fact that the strongly quadrupolar ^{14}N is not in the high-field limit. These effects are most clear in lower field spectra²² and can be seen in the 200 MHz high-temperature CRAMPS spectrum of aspartic acid (Figure 3) but also have been seen in well-resolved high field spectra.⁵ They offer the possibility of characterization of the bonding geometry and the quadrupole parameters for the nitrogen from the ^1H lineshapes²² as has been done for ^{13}C lineshapes for $^{13}\text{C}^{14}\text{N}$ pairs.^{23–26}

4 HYDROGEN BONDING: CHEMICAL SHIFT AND HYDROGEN EXCHANGE

For protons that participate in hydrogen bonding, there are well-known correlations between the shielding of the ^1H isotropic chemical shift, the ^1H shielding anisotropy, the ^2H coupling constant, and hydrogen bonding distances^{1,27–29} for

Figure 4 The ^1H chemical shifts of the amino acids in Figure 1 plotted against their O...O distances as indicated by crystallography. Filled circles show proton chemical shifts derived from our data, as shown in Figure 1; crystal structures for these compounds can be found in Rao,⁴⁰ Eggleston and Hodgson,^{41–43} Derissen et al.,⁴⁴ Bhat and Vijayan,⁴⁵ Sequeira et al.,⁴⁶ and Hamilton and Parthasarathy.⁴⁷ The open circles are from previous measurements in Harris et al.¹

small crystalline compounds. Quantification of hydrogen bonding is of great interest for studies in structural biology because of the role in recognition and conformational preferences. Solid state NMR could potentially be far more sensitive to details of hydrogen bonding and ionization states than crystallography. The chemical shifts for the acid protons for carboxyl groups in amino acids (shown in Figure 1) correlate with hydrogen-bonding length and this plot is shown in Figure 4 in filled circles. In comparison with previous measurements¹ which are entered here as open circles, our data encompass a rather restricted range because of the limited scope of compounds that are both relevant as model systems for proteins and sufficiently characterized. Clearly there is some scatter in the data but there is also a general trend that reproduces previous correlations.

Anisotropy of the proton shielding has been reported in a variety of solids with very simple structures; a thorough compilation and reviews are available.^{30–32} Many of these values were obtained from static multiple pulse measurements on either single crystals or powders or from rotation plots of the deuterium signal of a single crystal. The shielding anisotropy, $|\Delta\sigma| = |\sigma_{\perp} - \sigma_{\parallel}|$, is quite narrow (about 4–7 ppm) for alkyl or aromatic protons (except for methyl groups which are 1–2 ppm), but for some ionizable protons the anisotropy is more pronounced, with values of approximately 17 ppm for amides and 16–30 ppm for acids, alcohols, and water, but only about 5 ppm for amines. A detailed analysis of tensor values and orientations would presumably be useful in studying nonbonded interactions but is probably not possible in biological solids in the near future. Many complications affect the CSA measurements by CRAMPS, such as residual homonuclear and heteronuclear dipolar interactions, molecular motion, and chemical shift scaling. Magnetically dilute protons in organic solids give rise to spinning sidebands during low-speed MAS, and when the percentage of hydrogens that are replaced with deuterons is approximately 99% or larger these sidebands appear to be dominated by CSA effects (A. McDermott, unpublished).

A point of specific interest in solid state studies of hydrogen bonding is the fact that hydrogen bonds can have

profound effects upon reactivity in biological catalysis. For example, acid–base chemistry or proton mobility in the solid state is presumably strongly affected by local nonbonded interactions, a point which is relevant in many enzyme mechanisms. The geometric preferences of hydrogen bonds and the specific control of reactivity can be probed in the solid state studies since particular networks are arrested on an experimentally accessible timescale. Protons that participate in typical thermally driven and near-reversible exchange processes in proteins are found on the ‘ionizable’ hydrogen bonded groups such as carboxyl, imidazole, water, amine, alcohol, and guanidinium. The typical exchange timescales of microseconds to hours are presumably sensitive to the specific hydrogen-bonding geometry in a way that might be predicted by *ab initio*³³ or semiempirical methods. A systematic study of chemical exchange processes as a function of geometry in structurally characterized solids by NMR would help to clarify the theory of proton exchange.

Recent advances in ^1H NMR of deuterated simple model compounds for proteins show that such measurements of exchange processes are possible. Variable temperature two-dimensional (2D) methods applied to one example of a low symmetry hydrogen-bonded network of carboxylic acids and crystallographic water molecules demonstrated unambiguously that a proton is transferred between water and a carboxyl group⁶ in an activated process with a barrier of 37 kJ mol^{−1}. Additional measurements will be necessary for the purpose of creating a database that correlates rates of exchange with structural features.

5 2D CORRELATION WITH CARBON

The more ambitious goal of utilizing ^1H NMR for detailed structural analyses of amorphous solid materials or complex solid state macromolecules is not practical without addressing the problem of resolution of one ^1H resonance from the others of the same chemical functional group. The approach taken by solution NMR spectroscopy to correlate the ^1H resonance with nearby or attached heteronuclei is applicable in solids as well. The ^{15}N or ^{13}C NMR spectra in the solid state are considerably broader than solution spectra but nonetheless often allow distinction of a handful of selectively labeled residues. Two important classes of 2D H–X experiments for solid state NMR of H–X pairs are dipolar chemical shift correlation methods or ‘DIPSHIFT’³⁴ for determination of the bond distance to a great accuracy in a spin pair and heteronuclear correlation methods or ‘HETCOR’,^{35–37} which maps the chemical shifts of the X nucleus to nearby protons via the dipolar coupling. The latter is clearly the experiment of choice when more than one proton connected with the heteronucleus of interest should be resolved and rather approximate distance information will suffice. Our recent work with HETCOR and modified versions of the pulse sequence demonstrate the observation of longer H–X distances including C–O...H hydrogen bonds which appear as weak cross peaks. Rotor-synchronized transfer sequences have been used to increase the range of H–X distances probed by this method.³⁸ As an example, the HETCOR spectrum of alanyl aspartic acid is shown in Figure 5. In particular the ^1H – ^{13}C correlation peaks between the carboxyl groups around 170 ppm in the ^{13}C dimension and the acid proton near 12.5 ppm in the

Figure 5 Rotor-synchronized HETCOR spectrum of alanyl aspartic acid at 200 MHz and room temperature. Magnetization transfer was accomplished by 2.5 WIM-24 cycles per rotor period during four sequential rotor periods. The 90° pulse lengths were $3.2 \mu\text{s}$ for both channels. Experimental repetition time was 1.7 s. Data matrix was 80×512 points zero-filled to 512×512 with 20 Hz linebroadening in D_2 and a Kaiser window applied to D_1 . SSB = spinning sidebands

^1H dimension are indirectly connected pairs; several of the ^{13}C resonances show more than one ^1H cross peak.

Since essentially all of the resolution in the HETCOR experiment comes from the heteronuclear dimension, it is probably worthwhile to reiterate the virtues of such a 2D experiment in comparison with a one-dimensional (1D) heteronuclear measurement. Although detailed information about hydrogen bonding is available from heteronuclear NMR, the information from the ^1H shifts is often independent of that obtained from the heteronuclear shift. A case in point is the carboxylate group: the ^1H shift depends on the interaction of the detected acid proton with the nearest hydrogen bond acceptor, while σ_{22} of the ^{13}C shift depends on the distance between the carboxyl oxygen, which acts as a hydrogen bond acceptor, and the nearest proton.³⁹ The 2D HETCOR experiment provides the possibility of identifying the chemical nature of the hydrogen bonding partners to a carbon-containing functional group, even if the partners are water molecules. In a more practical light, we have found the HETCOR experiment to be quite useful in determining or confirming ^{13}C assignments for larger peptides and pharmaceuticals. As for disadvantages, obviously the time investment in such an experiment is enormously greater than that necessary for a 1D heteronuclear experiment. In the 2D spectra interpretation of the proton dimension is subject to similar complications as the CRAMPS experiment. In particular the intensities of the lines depend strongly on the presence or absence of mid-kHz motions.

Some of these issues are well illustrated with the spectrum of natural abundance alanyl aspartic acid. The three carbonyl-type carbons are readily identified by the HETCOR spectrum with one being a protonated carboxyl, one being deprotonated but hydrogen bonded to the protonated carbonyl, and the third being an amide carbonyl with no cross peak to the acid proton.

A strong hydrogen bond between the two carboxyl groups is indicated by both the deshielded acid proton (14 ppm) that was detected in the HETCOR spectrum and the σ_{22} value for the deprotonated carboxyl group (184 ppm) that was determined in 1D low-spinning CP MAS sideband analysis. Moreover the assignment of both the ^{13}C and ^1H dimensions can be verified by comparison of the ^1H shifts in the cross peaks of the carbonyl resonances with those in the methylene/methine region. From such a comparison one could have identified, for example, that the protonated carboxyl is alpha to a methylene while the deprotonated carboxyl is alpha to a methine. The fact that good sensitivity was obtained for a naturally abundant dipeptide implies that moderate-sized proteins can be studied by this approach if they are selectively labeled.

6 CONCLUSIONS

The long-established relationships between proton shift and hydrogen-bonding distances were confirmed in the more restricted data base of amino acids and peptides. Utilization of these 1D CRAMPS methods for proteins is unlikely because of the 0.3–1 ppm linewidths. These measurements might be of use in more complex solids if the spectrum is separated into two dimensions using correlations to attached heteronuclei in the HETCOR experiment. Demonstrations of HETCOR spectra on small peptides with naturally abundant ^{13}C demonstrate the requisite sensitivity for biological work and indicate the potential for measuring hydrogen bonding parameters and confirming assignments.

1 INTRODUCTION

Rotational resonance (RR) dates back to the early 1960s when Andrew and co-workers found that in magic angle spinning (MAS) experiments the T_1 relaxation times of the ^{31}P resonances from phosphorus pentachloride, which normally differed by an order of magnitude, were identical when the spinning speed was set equal to the frequency difference between two ^{31}P resonances in the sample.¹ An enhancement of the relaxation rates also occurred when the MAS speed was set to one-half or one-third of the frequency difference,² or more generally when the chemical shift difference between the two resonances ($\Delta\omega$) equaled an integral multiple of the MAS frequency (ω_r), namely $\Delta\omega = n\omega_r$. Since 1988, RR has been incorporated into a magnetization exchange experiment for measuring homonuclear dipolar couplings.^{3–6} In this article, I describe the RR magnetization exchange experiment and its application to biological systems.

Rotational resonance NMR is one of several solid state NMR approaches that have been developed recently for determining weak dipolar couplings under conditions of MAS.⁷ There are also MAS experiments for measuring homonuclear dipolar interactions that do not require RR, but restore the dipolar coupling through sequences of rf pulses (see *Homonuclear Recoupling Schemes in MAS NMR*). For measuring heteronuclear dipolar interactions, such as between ^{13}C and ^{15}N , Schaefer and co-workers have developed REDOR and TEDOR NMR (see *REDOR and TEDOR*).

The measurement of weak dipolar couplings in MAS experiments using any of these methods greatly enhances solid state NMR for studying biological systems since the dipolar couplings are directly related to internuclear distances which in turn provide constraints for the determination of molecular structure. The RR NMR and REDOR/TEDOR approaches have been shown to yield accurate measurements of internuclear distances. The distance limits that are accessible scale with the gyromagnetic ratios of the dipole-coupled spins. The upper limit for ^{13}C – ^{13}C measurements is $\sim 6.5\text{ \AA}$ and for ^{31}P – ^{31}P measurements is $\sim 10.5\text{ \AA}$. Structural studies can be designed where the measurement of only a few accurate distances can establish the conformation of an enzyme-bound substrate/inhibitor, or the local secondary structure and tertiary contacts in biological macromolecules.

2 METHODS

The RR NMR experiment targets isolated homonuclear spin pairs in which the two spins have different chemical shifts. The most commonly observed spins in biological systems are ^{13}C , ^{15}N , and ^{31}P . Specific isotope labeling is needed for ^{13}C and ^{15}N to enhance sensitivity and target selected sites. In order to measure the dipolar coupling between two labeled sites, such as an amino acid side-chain $^{13}\text{CH}_3$ group and peptide backbone $^{13}\text{C}=\text{O}$ group, and thereby estimate their internuclear separation, a magnetization exchange experiment is performed in which one of the ^{13}C resonances are selectively inverted while spinning at RR with a second ^{13}C resonance. The intensities of both ^{13}C resonances is then monitored as a function of a mixing time during which Zeeman magnetization is exchanged between the two sites. The rate of magnetization exchange is used to determine the internuclear distance.

2.1 Pulse Sequence

The RR NMR pulse sequence [Figure 1(a)] begins with proton cross polarization (CP; see *Cross Polarization in Solids*). Variable amplitude cross polarization (VACP) greatly facilitates the RR experiment.⁸ With conventional CP, the signal generated by CP is extremely sensitive to the exact amplitudes of the spin lock pulses at the high MAS rates often required for RR experiments. Under these conditions, the Hartmann–Hahn matching profiles are transformed into a series of sharp peaks separated by the MAS frequency and can exhibit resonance offsets such that CP from the two spins cannot be simultaneously optimized. A direct consequence of the CP amplitude sensitivity is that the absolute intensities of the resonances being monitored in the RR experiment can change substantially with small changes in the amplifier output or probe tuning. The VACP sequence solves this problem by producing stable intensities over a large range of Hartmann–Hahn mismatches.

After CP, the ^{13}C magnetization generated by the CP pulses is stored along the Z axis with a ^{13}C flip-back pulse. One of the two ^{13}C resonances is selectively inverted and magnetization is allowed to exchange between the two sites for a variable mixing period (τ_m). The distribution of ^{13}C signal at the end of this period is detected with a 90° pulse that flips the magnetization into the transverse plane for acquisition of the NMR signal. Strong proton decoupling is essential during the exchange time. Incomplete decoupling leads to a decrease in the observed magnetization exchange rate.⁶

2.2 RR NMR Spectra

Figure 1(b) illustrates magnetization exchange in a RR experiment with ^{13}C NMR spectra of a crystalline undecapeptide bearing ^{13}C labels at a side-chain methyl group (20 ppm) and backbone carbonyl (175 ppm) separated by $3.7\text{ \AA}$.⁹ The MAS rate has been set to the $n = 1$ RR condition where it exactly matches the 14 413 Hz frequency difference between the carbonyl and methyl carbon resonances at a carbon Larmor frequency of 90.4 MHz. The MAS speed must be regulated to within about $\pm 5\text{ Hz}$ in order to maintain the rotational resonance condition. The $^{13}\text{C}=\text{O}$ resonance has been selectively

Figure 1 (a) The pulse sequence for RR NMR experiments incorporating variable amplitude cross polarization (CP) on the proton channel. Magnetization generated by CP is stored on the Z axis with a 90° pulse and one of the two spins being studied is then selectively inverted. The spins are then allowed to exchange Zeeman magnetization during a variable mixing time (τ_m) and the distribution of signal at the end of this period is sampled with a 90° read pulse. (b) Carbon-13 RR NMR spectra of a crystalline undecapeptide at the $n = 1$ resonance condition. The carbonyl resonance has been selectively inverted with a low-intensity pulse while spinning at RR with a $^{13}\text{CH}_3$ resonance. The full spectrum using a 1 ms mixing time is shown together with inserts (offset for clarity) from spectra obtained at mixing times of 3, 5, 7, 9, and 11 ms. The internuclear distance, determined from the X-ray crystal structure of the peptide, is 3.7 Å, and the ^{13}C labeled peptide has been diluted $\sim 1:7$ with unlabeled peptide to prevent intermolecular transfer between the labeled sites. The MAS frequency of 14413 Hz was regulated to within ± 5 Hz for the duration of the experiment

inverted with a low-power $500\ \mu\text{s}$ pulse and the full spectrum was obtained with a short mixing time (1 ms) such that magnetization exchange has not had time to occur. As the mixing time is increased, the $^{13}\text{C}=\text{O}$ resonance returns to equilibrium and the coupled $^{13}\text{CH}_3$ resonance drops in intensity due to RR-driven exchange of magnetization between the two spins. The intensity changes are clearly seen in the offset plots taken from spectra at the longer mixing times. As an internal control, those peaks that are not at rotational resonance do not change in intensity during the experiment.

2.3 Generation and Interpretation of Magnetization Exchange Curves

The intensity changes observed in the RR experiment are translated into an internuclear distance by first generating a

Figure 2 Magnetization exchange curves for $^{13}\text{CH}_3$ – $^{13}\text{C}=\text{O}$ pairs showing the correlation between internuclear distance and the rate of magnetization exchange. The data have been obtained from five crystalline peptides bearing pairs of specific ^{13}C labels separated by 3.7, 4.5, 4.8, 5.1, and 6.8 Å. The distances are known independently from the X-ray structure of the peptide. The curves have been normalized to an initial value of 1.0 and have been corrected for natural abundance contributions

magnetization exchange curve. This is a plot of the net signal from the two exchanging resonances as a function of the mixing time. The signal is calculated as the intensity difference between the noninverted and inverted resonances to account for magnetization present in both of the exchanging spin populations. Two considerations that are crucial in calculating these curves are (1) establishing an accurate intensity for the first time point that is used to normalize the curve to an initial value of 1.0 and (2) accounting for natural abundance background signals and exchange.

Figure 2 presents a set of $n = 1$ magnetization exchange curves for $^{13}\text{CH}_3$ – $^{13}\text{C}=\text{O}$ pairs separated by 3.7, 4.5, 4.8, 5.1, and 6.8 Å.⁹ These data were obtained on the crystalline undecapeptide described above where the internuclear distances are known independently from a high-resolution crystal structure. The magnetization exchange rates scale with internuclear distance, with the largest changes in intensity observed with the shortest distance. The resolution of the experiment is in the range of 0.1–0.2 Å (below about 5 Å) and the upper limit for observing RR-driven magnetization exchange is on the order of 6.5 Å. These ‘standard’ curves provide one way of determining unknown distances between similar functional groups.

A second approach for determining internuclear distances from the magnetization exchange curves is by computer simulations.⁵ Simulations of the RR process reveal that the rate of magnetization exchange depends on several parameters in addition to the internuclear distance. These include the orientation and chemical shift anisotropy (CSA) of each spin as well as the zero quantum T_2 relaxation which accounts in a global way for several processes influencing magnetization exchange that are not driven by rotational resonance. The size and orientation of the chemical shift tensor for each site can often be based on model compound data. Importantly, the dependence of magnetization exchange on both the CSA and the tensor orientations is minor when spinning at the $n = 1$ RR condition. The zero quantum T_2 relaxation, however, has a considerable influence on the exchange rate, especially for weak dipolar couplings. A major contribution to this term can come from residual proton coupling. A lower limit for

the zero quantum T_2 , corresponding to a lower limit for the distance estimate, can be based on the observed linewidths of the exchanging resonances. Inhomogeneous line broadening leads to an underestimate of the internuclear distance if the observed linewidth is used to estimate the zero quantum T_2 .¹⁰ An upper limit on the zero quantum T_2 , and a corresponding upper limit on the distance estimate, can be taken from the linewidths observed for similar functional groups in model compounds.

3 BIOLOGICAL APPLICATIONS

Rotational resonance measurements have been most effective for studying the structure of enzyme-bound substrates and inhibitors and for characterizing specific internuclear distances in membrane systems. The studies on enzyme complexes are often motivated by the lack of a high-resolution crystal structure or by high molecular weights which limit the application of solution NMR approaches. These experiments are facilitated in many cases by the relative ease of specific isotope labeling of a small substrate or inhibitor molecule. In a similar fashion, biological membranes are large heterogeneous systems that are not well suited for study by single crystal diffraction and solution NMR methods. Rotational resonance NMR has been used increasingly for structural studies on membrane proteins and lipids. We discuss below several examples that illustrate these applications.

3.1 Inhibitors and Substrates

The conformation of enzyme-bound substrates and inhibitors can be determined by measurements of both internuclear distances and molecular orientations using RR methods. Rotational resonance measurements have been used to establish the mechanism of inactivation of D-alanyl-D-alanine ligase by an aminoalkyl dipeptide phosphinate inhibitor.¹¹ The enzyme normally catalyzes ligation of D-alanine to form a dipeptide using ATP-dependent phosphorylation in the first step of the reaction. The peptide inhibitor is thought to become phosphorylated in the active site of the protein producing an enzyme complex containing ADP and a phosphoryl phosphinate inhibitor. The dipolar coupling measured between the ^{31}P site on the inhibitor and the ^{31}P group of a phosphate ester corresponded to a ^{31}P – ^{31}P distance of $2.7 \pm 0.2 \text{ \AA}$. This strongly implied that the two species were bridged in a P–O–P linkage. Two other resonances in the ^{31}P spectrum assigned to ADP did not exhibit intensity changes when placed on RR with the inhibitor, indicating that these ^{31}P atoms were more than 5 Å from the phosphinate.

The RR-driven magnetization exchange is largely insensitive to the orientation and CSA of the two exchanging sites at the $n = 1$ condition.⁵ However, the exchange rates become increasingly sensitive to these parameters with higher RR orders ($n > 2$). Recently, this orientation dependence has been exploited to determine the conformation of transition state analogs bound to triose phosphate isomerase.¹² It was found that the phosphate of phosphoglycolic acid had an inplane orientation relative to the carboxyl group when bound to the enzyme, providing an explanation for the lack of phosphate elimination during catalysis.

3.2 Membrane Proteins

Solid state NMR has been applied extensively to study membrane systems, particularly lipid dynamics (see *Bilayer Membranes: Deuterium and Carbon-13 NMR* and *Bilayer Membranes: Proton and Fluorine-19 NMR*). Rotational resonance NMR provides one of the only approaches for generating high-resolution distance constraints in these systems. The conformation about several bonds in the retinal prosthetic group of bacteriorhodopsin (see *Bacteriorhodopsin and Rhodopsin*), a 26 kDa protein, has been determined by RR methods [Figure 3(a)]. These studies are conceptually similar to those of enzyme-bound inhibitors where the conformation of a specifically labeled molecule is studied complexed to a large protein. The conformation of the C-6–C-7 bond connecting the β -ionone ring to the conjugated retinal chain was determined to be *s-trans* and the configuration of the C=N bond linking the retinal chromophore to a lysine side chain in the interior of the protein was determined to be *trans* in bR₅₆₈ and *cis* in bR₅₄₈.¹³ Rotational resonance measurements have further established that the C=N bond has an *anti* configuration in an M form of the protein.¹⁴

Rotational resonance experiments can also be designed to establish the secondary structure and tertiary interactions of the protein components in membranes [Figure 3(b)].⁶ Most proteins span membrane bilayers in α -helical secondary structures. Interactions between helices serve to stabilize the protein tertiary structure or drive protein dimerization. Furthermore, the transmembrane regions of membrane proteins can form separate folded and interacting domains, and can be studied independently of the soluble extramembraneous domains. Internuclear distance measurements between ^{13}C sites that are separated by 2–4 residues in the amino acid sequence can be used to probe local secondary structure. The distance between a C=O backbone carbonyl and the α -carbon of a residue separated by 2–3 residues is ~ 4.6 – $5.2 \text{ \AA}$ in a helical geometry, but greater than 8 Å in an extended β -conformation. These intrahelical distances are well within the distance limits of RR measurements.

Similarly, the contacts between interacting helices can be established using RR NMR. The backbone to backbone separation of interacting helices is roughly 5 Å. The side chains of opposing helices are in van der Waals contact within this region. Rotational resonance measurements on peptides corresponding to the transmembrane domain of glycophorin A have demonstrated that RR can be used to probe both local secondary structure and helix interactions.^{6,15} Glycophorin is an integral membrane protein that spans the cell membrane of erythrocytes in a single helical stretch of ~ 23 hydrophobic amino acids. Interactions between helices stabilize a protein dimer. Intramolecular RR measurements have shown that the transmembrane domain of glycophorin forms a helix in membranes. Intermolecular RR measurements have suggested that the side-chain valines of residues 80 and 84 are packed in the helix interface near glycine residues 79 and 83 suggesting that these residues are packed in the interface in a ‘knobs-in-holes’ arrangement.

3.3 Other Systems

Rotational resonance NMR has also been used to study the conformation of lipids in membranes^{6,10} and the local

Figure 3 Models of membrane proteins illustrating internuclear distances that have been measured using RR NMR. (a) Schematic representation of bacteriorhodopsin, a 26 kDa integral membrane protein that spans the cell membrane with seven α -helical transmembrane domains (only three helices depicted). The retinal chromophore is buried in the hydrophobic interior of the protein. Rotational resonance NMR has been used to establish the conformation of the C-6-C-7 single bond and the configuration of the C=N double bond by measuring the distances between specific ^{13}C labels introduced into the retinal chromophore and lysine side chain of the protein. (b) Schematic representation of the transmembrane domain of glycoporphin A. Rotational resonance NMR has been used to establish the local secondary structure and tertiary contacts in 29-residue peptides corresponding to the transmembrane sequence of the protein. Magnetization exchange rates were measured between $[^{13}\text{C}]$ methyl groups in the targeted hydrophobic sequence -G₇₉-V₈₀-M₈₁-A₈₂-G₈₃-V₈₄- (G = glycine, V = valine, M = methionine, A = alanine) located in the middle of the transmembrane domain and specific $[^{13}\text{C}]$ carbonyl labels along the peptide backbone across the dimer interface

secondary structure of amyloid peptides in fibrillar aggregates.¹⁶ In both cases, specific ^{13}C labels were incorporated into a low molecular weight component of a much larger complex. These studies, together with those on the enzyme complexes and membrane proteins discussed above, illustrate the range of problems that can be addressed using RR NMR. Future prospects for RR NMR lie in the further development of both NMR and biochemical methods for targeting specific sites in biological macromolecules.

1 INTRODUCTION

The structural investigation of peptides, polypeptides, proteins, and other biopolymers in the solid state is being pursued increasingly by means of high-resolution solid state NMR.^{1–8} Most of the biopolymers considered here consist of repeating sequences of peptide bonds with 20 different types of substituent at the α carbon. The secondary structures of these biopolymers are classified as α -helix, β -sheet, ω -helix, and so on, by means of a set of dihedral angles (ϕ , ψ).

In the solution state, the NMR chemical shifts of biopolymers with internal rotations are often the averaged values for all internal rotations because of rapid interconversion by rotation about peptide bonds. In the solid state, however, chemical shifts are often characteristic of specific conformations because of highly restricted rotation about the peptide bonds. The NMR chemical shift is affected by a change in the electronic state arising from the conformational change.⁹ NMR chemical shifts in the solid state, therefore, provide useful information about the electronic state and conformation of a biopolymer with a fixed structure.¹⁰

The present article concentrates on the use of solid state ^{13}C , ^{15}N , and ^{17}O NMR studies in the structural investigation of biopolymers such as polypeptides, proteins, and similar compounds.

2 SOLID STATE ^{13}C NMR OF POLYPEPTIDES AND PROTEINS

2.1 Synthetic Polypeptides

Synthetic polypeptides consist of repeating sequences of certain amino acids and their structures are not as complicated as those of proteins. For this reason, synthetic polypeptides are sometimes used as model compounds for proteins. Their conformations are classified as α -helix, β -sheet, ω -helix, and so on. High-resolution solid state ^{13}C NMR spectroscopy has proved to be a very powerful tool for determining the structure of polypeptides in the crystalline state.^{1,5–8} It has been demonstrated that the ^{13}C chemical shifts are related to particular conformations. Carbon-13 CP MAS NMR spectra of

Figure 1 Plots of the ^{13}C chemical shifts of oligo-L-Ala and poly-L-Ala against the number-average degree of polymerization ($\overline{\text{DP}}_n$)

solid poly(L-alanine) ($[\text{Ala}]_n$) show the C- α , C- β , and C=O carbon signals to be well resolved between the α -helix and β -sheet forms.¹¹ The ^{13}C chemical shifts are plotted against the number-average degree of polymerization in Figure 1. Clearly, ^{13}C chemical shifts of $[\text{Ala}]_n$ ($n > 16$) are unchanged for the peptides of various molecular weights within experimental error, and thus can serve to characterize the α -helix form. The chemical shifts of the C- α and carbonyl carbons of the α -helix are displaced significantly to high frequency (downfield) by 4.2 and 4.6 ppm, respectively relative to those of the β -sheet form, while the chemical shift of the C- β carbon of the α -helix is displaced to low frequency by about 5 ppm with respect to that of the β -sheet (−5.0 ppm). For this reason, the value of the ^{13}C chemical shift can be used to describe the local conformation.¹² In addition, the ^{13}C chemical shifts of randomly coiled poly(L-alanine) in trifluoroacetic acid solution have values between those of the α -helix and β -sheet forms.

The existence of such characteristic displacements of ^{13}C chemical shifts is not limited to the Ala residue. In Table 1 are summarized the ^{13}C chemical shift values of various amino acid residues in the α -helix and β -sheet forms.^{5,6} Here it is seen that the C- α and C=O peaks of the α -helix form are all displaced to high frequency with respect to those of the β -sheet form, which is consistent with the data of poly(L-alanine). The absolute ^{13}C chemical shifts of the C- α and C- β carbons are affected by the chemical structure of the individual amino acid residues and can be used effectively for conformational studies of particular amino acid residues in polypeptides and proteins. On the other hand, the C=O chemical shifts do not seem to be affected by residue structure and can be used for diagnosing the main chain conformation.

Poly(β -benzyl L-aspartate) (PBLA) in the solid state adopts various conformations such as a right-handed $\alpha(\alpha_R)$ -helix, a left-handed $\alpha(\alpha_L)$ -helix, a left-handed $\omega(\omega_L)$ -helix, and a β -sheet form depending upon the temperature. The measured values for the ^{13}C chemical shifts depend significantly on the conformations of the peptide as shown in Table 2.¹³ Variable temperature ^{13}C CP MAS NMR spectra of PBLA are shown in Figure 2.¹⁴ The temperatures of the conformational changes of PBLA are indicated in the Figure. From this, it is clear that

Figure 2 Variable temperature ^{13}C CP MAS TOSS NMR spectrum of poly(β -benzyl L-aspartate) in the solid state at various temperatures: dashed line, α_R -helix form; light solid line, ω_L -helix form; bold solid line; β -sheet form

the conformational changes α_R -helix $\rightarrow$ ω_L -helix $\rightarrow$ β -sheet occur with increasing temperature.

The conformations of polypeptides such as poly(L-alanine), polyglycine, and so on in the solid state are in many instances quite fixed. However, additional types of conformation can be formed when a small amount of guest glycine¹⁵ or L-Ala¹⁶ residues are incorporated into the host polypeptides. For example, solid state ^{13}C CP MAS NMR spectra of PBLA

containing $[3-^{13}\text{C}]\text{L-Ala}$ residues have been measured. The Ala C- β carbon shows significant displacements of the ^{13}C chemical shift depending on the conformational change.

Using the reference data, the helical sense of the ω -helix of poly(L-phenylalanine) has been shown to be right-handed, and this could not have been determined absolutely by X-ray diffraction. Furthermore, the side-chain conformation-dependent ^{13}C chemical shifts of this polymer and the L-phenylalanine residue in oligopeptides have been determined.¹⁷

The principal values of the ^{13}C chemical shift tensors (σ_{11} , σ_{22} , and σ_{33}) determined from the ^{13}C powder pattern spectrum are valuable as parameters for obtaining structural information which can be related to the electronic state more directly than the isotropically averaged value [$\sigma_{\text{iso}} = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3$].¹⁰ Nevertheless, very few data are available for the ^{13}C chemical shift tensor for carbon atoms in peptides. There have been a few studies of conformation using ^{13}C chemical shift tensors of polypeptides in the solid state. Solid state ^{13}C CP MAS NMR spectra of a variety of polypeptides containing $[1-^{13}\text{C}]\text{glycine}$ residues as a minor component (<8%) have also been recorded. This was to obtain the ^{13}C isotropic average chemical shifts, and the principal values of the chemical shift tensors of the glycine (Gly) carbonyl carbon in β -sheet, α -helix, ω -helix, and 3_1 -helix forms.¹⁵ The last two conformations were obtained only when Gly residues were incorporated into the homopolypeptides. It was found that the magnitudes of displacements of chemical shifts upon conformational changes are larger for σ_{22} and σ_{33} than the

^aDP = degree of polymerization.

isotropic chemical shift values, while σ_{11} is almost unaffected by any conformational change.

A solid state ^{13}C NMR study of some polypeptides containing $[2-^{13}\text{C}]$ glycine residues has been carried out in order to clarify a conformational effect on the ^{13}C chemical shift tensors. It was found that the isotropic chemical shifts and principal values of the chemical shift tensor of Gly C- α incorporated in some homopolypeptides are displaced.

Hydrogen bonding plays an important role in the adoption of any specific conformation in peptides and polypeptides in the solid state. The effect of hydrogen bonding on the solid state ^{13}C chemical shifts of carbonyl carbons in peptides has been examined. Carbon-13 chemical shifts were determined for a series of oligopeptides containing glycine (Gly), L-Ala, L-valine, and L-leucine residues, for which the crystal structures were already available from X-ray diffraction studies. It was found that the ^{13}C chemical shifts of the carbonyl carbons in the $-\text{C}=\text{O} \cdots \text{H}-\text{N}-$ type of hydrogen bond move linearly to high frequency with a decrease in the hydrogen bond length ($R_{\text{N}-\text{O}}$) as $\delta = a R_{\text{N}-\text{O}} + b$ (ppm). For the Gly, L-Ala, L-valine, and L-leucine residues, a and b are -12.4 and 206 , -21.7 and 237.5 , -14.2 and 215.4 and -10.0 and 202.2 ppm, respectively.^{18,19} Using these relations, the hydrogen-bond length can be determined from the observed ^{13}C chemical shift values for the carbonyl carbons. These experimental results were explained by using ^{13}C chemical shift calculations based on the finite perturbation theory (FPT) intermediate neglect of differential overlap (INDO) method.

The conformational structures of poly(α -L-glutamic acid) [poly(Glu)], poly(α -L-aspartic acid) [poly(Asp)] and irregular poly(α,β -D,L-Asp) in the solid state have been studied by means of ^{13}C CP MAS NMR in conjunction with results from X-ray diffraction and infrared spectroscopy studies.²⁰ From these, it has been shown that poly(Glu) and poly(Asp) in the free acid form exhibit both α -helical and β -sheet forms, whereas the random coil form predominates in their sodium salts. Both the free acid and sodium salt of poly(α,β -Asp) exist predominantly in the random coil form. It turns out that the sodium salts are especially suitable for determining the NMR characteristics of the random coil conformation in the solid state.

2.2 Proteins

2.2.1 Fibrous Proteins

Since fibrous proteins generally have periodic amino acid sequence and higher order structures, the clarification of their

fine structure in the solid state becomes very important not only when discussing the physical and chemical properties, but also when obtaining information about the molecular design of synthetic polypeptides. Indeed, a comparison of some fibrous proteins and their model synthetic polypeptides has been carried out. The conformation-dependent ^{13}C chemical shifts are useful for the determination of the conformational features of fibrous proteins.

Silk fibroin is one of the fibrous proteins having a simple amino acid composition, and isotopic enrichment can be performed easily. More detailed analyses of static or dynamic structures have been made by solid state NMR.^{1,21,22} The amino acid composition of silk varies with the species of silkworm. In reflecting the higher Ala content of *Phylosamia cynthia ricini* fibroin it has been shown that the ^{13}C chemical shifts of the Ala residues of a dried sample, taken from the silk gland of *P.c. ricini*, are identical to those of the α -helical $[\text{Ala}]_n$. In contrast, the cocoon of *P.c. ricini* was found to have an antiparallel β -sheet form, as determined from the ^{13}C chemical shifts of the Ala and serine (Ser) residues. On the other hand, the ^{13}C peaks of the Ala and Gly residues of the silk II form of *Bombyx mori* silk fibroin are in good agreement with those of $[\text{Ala-Gly}]_n$ II as well as $[\text{Gly}]_n$ II and $[\text{Ala}]_n$ in the β -sheet form. The ^{13}C chemical shifts of samples taking the silk I form are significantly displaced from those of the silk II form. Models for the silk I structure of *B. mori* silk fibroin have been proposed on the basis of ^{13}C NMR data, X-ray diffraction data, and conformational energy calculations.

Collagen is composed of a triple-stranded helix. The individual triple chains are composed of the repeating pattern, $[\text{Gly-X-Y}]_n$, where X and Y are frequently occupied by proline (Pro) and hydroxyproline residues, respectively. Torchia and co-workers^{23,24} have reported substantial work on the molecular dynamics of collagens by means of multinuclear solid state MR, using isotopically labeled samples which were obtained by cultivation techniques. Saito et al.²⁵ have found that most of the ^{13}C signals of collagen fibrils from bovine tendon and skin are in good agreement with those of $[\text{Pro-Gly-Pro}]_n$, although some peaks characteristic of the collagen are slightly displaced from those of the model polypeptides. All of the peaks of collagen fibrils have been assigned on the basis of computer simulation by utilizing amino acid composition and chemical shift data from the solid state and solution.

Carbon-13 CP MAS NMR spectra of tropomyosin, one of the muscle proteins, were measured in the solid state, in order to elucidate the higher order structure of the protein via the observation of the ^{13}C chemical shifts of the amino acid residues and their mobility. The higher order structure of tropomyosin is a right-handed α -helix coiled-coil structure,

Figure 3 A schematic picture of the cross-section of the coiled-coil structure in tropomyosin (top), and the typical ^{13}C CP MAS NMR spectrum of tropomyosin at room temperature (bottom)

which contains two different sites. These are characterized by an internal hydrophobic site and an external hydrophilic site (Figure 3). A typical ^{13}C CP MAS NMR spectrum for tropomyosin in the solid state is shown in Figure 3.²⁶ Since the Ala residue is one of the major components, the ^{13}C signal which appears at 15–17 ppm can be assigned readily to the Ala C- β carbons, and it is seen that this signal consists of two peaks. Figure 4 shows the expanded Ala C- β signal, measured using the inversion–recovery method. These peaks indicated that there are at least two kinds of Ala C- β carbons. Furthermore, the carbon atoms contributing to the peak at 15.8 ppm have a larger value of T_1 than those at 16.7 ppm. This indicates that the former carbons are more mobile than the latter carbons, because the Ala C- β carbons in tropomyosin have correlation times with values appearing in an extremely narrow region at room temperature. The distance between the two α -helical axes in the coiled-coil structure is shorter than in coiled-coil helices which are packed in parallel in native muscle, as shown from X-ray studies. Therefore, it can be argued that the mobility of the Ala C- β carbon atoms in the internal site is expected to be more restricted than that in the external site. The two peaks at 15.8 and 16.7 ppm therefore are assigned to the Ala C- β carbons in the external and internal sites of the coiled-coil structure, respectively.

Native wool fiber consists of intermediate filaments composed of low-sulfur-containing proteins which are embedded in a nonfilamentous matrix. The nonfilamentous matrix

Figure 4 The expanded ^{13}C NMR spectra of the Ala C- β carbon atoms of tropomyosin, measured using the inversion–recovery method at room temperature. Recovery time, t : (a) 10 ms; (b) 500 ms; (c) 3500 ms

usually consists of two classes of proteins; one is a high-sulfur-containing protein and the other is a protein containing Gly and tyrosine (Tyr) residues. Wool keratin can be divided into three main fractions after reducing the disulfide bonds and protection of the resulting thiol groups with iodoacetic acid to form *S*-carboxymethylkerateine (SCMK). The solid state ^{13}C CP MAS TOSS NMR spectra of wool and four kinds of SCMKs extracted from low-sulfur fractions (SCMKA), helix-rich fragments (SCMKA-hf), high-sulfur fractions (SCMKB), and high-Gly-Tyr fractions (HGT) are shown in Figure 5.^{27,28} For characterization of the main-chain conformation of polypeptides and proteins in the solid state, it is very useful to use the ^{13}C chemical shift value of the main-chain carbonyl carbon, because it is strongly influenced by the conformation of the main chain but not by the type of amino acids and/or a specific amino acid sequence. Hence, it can be argued that the lineshape of the ^{13}C signals in the carbonyl region for proteins reflects the main-chain conformation.

The carbonyl ^{13}C signal can be resolved into four peaks by computer fitting. The relative intensity of the high-frequency peak at about 176 ppm corresponds to the proportion of the α -helix component, because this peak comes from the main-chain carbonyl carbons in the α -helix form. The proportion of

Figure 5 ^{13}C CP MAS TOSS NMR spectra of (a) wool, (b) SCMKA, (c) SCMKA-hf, (d) SCMKB, and (e) HGT, and their expanded spectra of the carbonyl carbon region. Arg = arginine, Thr = threonine, Val = valine, Ile = isoleucine, Cys = cysteine, Phe = phenylalanine

the α -helix component increases in the order: wool, SCMKA, SCMKA-hf. On the other hand, the low-frequency peak at 172 ppm is characteristic of the main-chain carbonyl carbons in the β -sheet form. On the basis of the above assignment, it can be said that the β -sheet form is predominant in SCMKB and HGT. These findings are also confirmed from the peaks in other carbon regions. Furthermore, it is suggested that the coiled-coil structure exists in wool, SCMKA, and SCMKA-hf,

because the ^{13}C chemical shift values of the Ala C- β carbons in these samples coincide, within experimental error, with that of the Ala residue located in the internal site of the coiled-coil structure in tropomyosin.

This conformational analysis, using conformation-dependent ^{13}C chemical shifts, has been applied to investigate the conformational transition of SCMKA induced by stretching, heating, or steam-treating. The β -sheet form appears and the proportion

Figure 6 Expanded ^{13}C CP MAS TOSS NMR spectra for the carbonyl carbon region in SCMKA films cast from aqueous solution

of the α -helix form decreases upon stretching and steam-treating as shown in Figure 6.²⁸ For the SCMKA heated at 200 °C for 3 h in vacuo, the ^{13}C CP MAS spectrum shows that each peak is broader than those of other treated specimens. This indicates the existence of various conformations and/or different microenvironments in the heated SCMKA. Thus, it can be said that the random coil form appears by heating. From X-ray diffraction measurements, the α -helix form completely vanishes in SCMKA heated under the same conditions. However, Figure 6 shows that the α -helix form remains to an appreciable extent in the heated sample, although the random coil form also appears. The difference between the results from X-ray diffraction and NMR spectroscopy studies suggests that only the packing of the ordered structure (the α -helix form) in SCMKA is disrupted by heating, but that the secondary structure is retained. On the other hand, in the case of the structural transition for the same protein, the change of the lineshape for the α -methine carbons can be attributed mainly to the conformational change.

The dynamics and structure of mouse keratin intermediate filaments has been investigated by solid state ^{13}C and ^2H NMR spectroscopy, using isotopically labeled samples.²⁹

2.2.2 Membrane Proteins

The structural and dynamic analysis of membrane proteins is readily achieved by solid state ^{13}C NMR. The reasons are

as follows: firstly, biological membranes greatly restrict the motion of embedded proteins and consequently are difficult to study by solution NMR methods; secondly, only a few membrane proteins have been crystallized and studied by X-ray diffraction methods; thirdly, if the membrane protein is uniaxially oriented in the lipid, there is the advantage of being able to determine the structure at the atomic level by NMR as well as X-ray crystallography. Further, since phospholipids coexist in many cases in membranes, the NMR method is still suitable because of its ability to observe selectively by means of isotopic labeling, multinuclear MR, and utilizing the differences of relaxation times. Thus phospholipids, for example, are readily and selectively studied by solid state NMR methods using specifically ^{31}P NMR.³⁰

The ^{13}C CP MAS spectra of ^{13}C -labeled gramicidin A (GA) were measured to determine directly the structure of this peptide in a lipid membrane.³¹ The seven GA analogs, each labeled at a single carbonyl group of each of some amino acid residues, were synthesized by the solid phase method. These ^{13}C -labeled GAs were incorporated into aligned multilayers of dimyristoylphosphatidylcholine or diether lipid bearing 14- or 16-carbon chains, at a 1:15 peptide:lipid molar ratio. Carbon-13 CP NMR spectra were obtained at several temperatures and over a range of sample orientations with respect to the spectrometer magnetic field. The observed chemical shielding anisotropies indicate that all of the labeled carbonyl bonds are oriented almost parallel to the molecular long axis and perpendicular to the lipid bilayer plane. These orientations are consistent with GA forming a $\beta 6.3$ single-strand helix that is oriented parallel to the methylene chains of the lipid molecules. Comparison of the linewidths from labeled residues that are in the innermost turn of the helix, and in the turn nearest the lipid bilayer surface suggests that although the peptide behaves largely as a right-handed barrel, segments of the peptide close to the membrane surface possess greater motional freedom.

Bacteriorhodopsin and rhodopsin are integral membrane proteins that contain the vitamin A aldehyde, retinal, as a photoreactive chromophore. Many solid state NMR studies on the structure and environment of the retinal chromophore in these proteins have been reported, using mainly specifically ^{13}C -labeled retinals.^{2,32,33} It may reasonably be said that the structure of retinal in bacteriorhodopsin and rhodopsin has been determined by solid state NMR. Hence, solid state NMR is an extremely important experimental procedure in investigating the mechanism of sight. Most recently, the spectrum of ^{13}C -labeled bacteriorhodopsin in purple membranes was recorded. On the basis of the ^{13}C CP MAS NMR experiments, a discussion has been presented of the change of the manner of mutual orientation between α -helices as induced by hydration/dehydration.

Also, soluble proteins such as enzymes, conjugated proteins such as glycoproteins, and proteins which are in more complex systems have been investigated by solid state NMR.^{34–36}

3 SOLID STATE NMR STUDIES OF ^{15}N IN SYNTHETIC POLYPEPTIDES

It has been demonstrated that the isotropic ^{15}N chemical shifts of systems such as poly(Gly) (PG), poly(L-Ala), poly(L-leucine), poly(L-isoleucine) poly(L-valine), poly

Figure 7 Diagram of the observed isotropic ^{15}N shielding of some homopolypeptides $[\text{X}]_n$ with various conformations (α -helix, β -sheet, α_L -helix, ω_L -helix, PG I, PG II, PP I, and PP II forms). Leu = leucine, Ile = isoleucine, Val = valine, Glu = glutamic acid

(L-phenylalanine), poly(γ -methyl L-glutamate), poly(β -benzyl L-aspartate) and poly(L-Pro) (PP) in the peptide backbone of polypeptides in the solid state exhibit a significant conformation-dependent change. Both experimental observation and theoretical calculation confirm this.^{37–39} The σ_{iso} for the α -helix form (97.0–99.2 ppm) appears to low frequency by about 1.2–10.0 ppm with respect to that for the β -sheet form (99.5–107.0 ppm) of polypeptides, which obviously depends on the structure of the individual amino acid residue, as shown in Figure 7 (relative to $^{15}\text{NH}_4\text{NO}_3$). Some ^{15}N chemical shift differences are rather small, but are meaningful in the context of polypeptides. The variations of the σ_{iso} for various kinds of polypeptides are about 2.5 ppm in the α -helix form and about 7.5 ppm in the β -sheet form. In addition, the σ_{iso} of the β -sheet form of the L-leucine, L-valine, and L-isoleucine residues, which possess alkyl side chains, appear to high frequency with respect to that of the L-Ala residue. In contrast, the σ_{iso} value for the β -sheet form of the L-Asp(OBzl), L-Glu(OBzl), and L-Glu(OMe) residues (where Glu = glutamic acid), which possess a side-chain ester, is to low frequency with respect to that of the L-Ala residue. These results indicate that the ^{15}N chemical shift difference between the α -helix and β -sheet forms depends on the side-chain structure of individual amino acid residues.

Further, σ_{iso} gives information about the helix sense (α_R -helix or α_L -helix) of poly(β -benzyl L-aspartate) (ω -helix: 99.2 ppm; α_L -helix: 97.0 ppm).⁴⁰ In addition, the ^{15}N chemical shift value of PBLA with low molecular weight (β -sheet form) is identical with that of PBLA with high molecular weight (β -sheet form), indicating that the ^{15}N chemical shift of solid polypeptides is independent of the chain length, if no conformational changes occur. Accordingly, the ^{15}N chemical shift depends mainly on the conformation and side-chain structure of individual amino acid residues. In order to support this view theoretical calculations of ^{15}N chemical shifts are required, using the electronic states derived by quantum chemical methods. The relative ^{15}N NMR chemical shift of a dipeptide fragment forming hydrogen bonds with two formamide molecules has been calculated using the FPT INDO theory.³⁷

The relation between the isotropic ^{15}N chemical shift or chemical shift tensor and the structures of various kinds of synthetic copolypeptides in the solid state have been studied.^{38–40} It was found that the ^{15}N chemical shifts indicate strong neighboring sequence effects.

An analytical method for the determination of dihedral angles of the GA backbone from solid state ^{15}N NMR spectroscopic data has been demonstrated.^{31,41} Advantage is taken of the ^{15}N – ^1H and ^{15}N – ^{13}C dipolar interactions as well as the ^{15}N chemical shift interaction in the oriented samples. The dihedral angles for the L-Ala₃ site are determined by obtaining the NMR data for both the Gly₂–L-Ala₃ and L-Ala₃–D-leucine₄ peptide linkages. Two possible sets of torsion angles for the L-Ala₃ site are obtained ($\phi, \psi = -129^\circ, 153^\circ$ and $-129^\circ, 122^\circ$), both of which are consistent with a right-handed α -helix. In addition, the dynamics of the backbone of GA in dimyristoylphosphatidylcholine bilayers have been investigated using solid state ^{15}N NMR.⁴¹ Nitrogen-15 CP NMR spectra of single-site ^{15}N -labeled GA at 8 °C were analyzed to yield a spatial model for local backbone motion. This model includes the axis of motion, the mean orientation, and the maximum amplitude of displacement for individual peptide planes. Specific sites in the first turn of the amino terminus were investigated, with emphasis on the L-Ala₃ and D-leucine₄ linkages, for which the orientation of the ^{15}N chemical shift tensor with respect to the molecular frame has been determined.

4 SOLID STATE ^{17}O NMR OF SYNTHETIC POLYPEPTIDES

The oxygen atom is an important atom in the hydrogen bonding structure in peptides and polypeptides. Nevertheless, a solid state ^{17}O NMR study of peptides and polypeptides has never been carried out, to our knowledge. This is due to the very low sensitivity of solid state ^{17}O NMR measurements which arises for two reasons. One is that the ^{17}O nucleus is in very low natural abundance, 0.037%. The other is that the ^{17}O nuclear spin quantum number (I) is $\frac{5}{2}$, which is a quadrupolar nucleus, and so the ^{17}O signal is broadened by nuclear quadrupolar effects in the solid. On the other hand, solution state ^{17}O NMR spectroscopy has been employed successfully to elucidate a number of structural problems in organic chemistry,⁴² because the ^{17}O signal becomes very sharp due to the removal of quadrupolar interaction by isotropic fast reorientation in solution. For example, as the oxygen atom is directly associated with the formation of hydrogen bonds, hydrogen bonding for the carbonyl group

in various compounds often results in large low-frequency shifts of the carbonyl ^{17}O NMR signal.⁴³ From these results, solution state ^{17}O NMR has been established as a means of investigating structural characterizations.

Clearly therefore, solid state ^{17}O NMR does offer a unique opportunity for understanding the hydrogen-bonding structure in solid peptides and polypeptides. Kuroki et al.⁴⁴ have observed high-resolution ^{17}O NMR spectra of systems with a wide range of hydrogen bond length, of PG I, PG II, glycylglycine (GlyGly) and glycylglycine nitrate (GlyGly·HNO₃) in the solid state, in order to obtain three kinds of NMR parameters: chemical shift, the quadrupolar coupling constant (e^2qQ/h) and the asymmetric parameter (η_Q), and to understand the relationship between the hydrogen bonding structure and these NMR parameters.

Static ^{17}O CP NMR spectra of GlyGly were observed at 36.6, 54.2, and 67.8 MHz. The spectra at 36.6 and 54.2 MHz consist of two major split signals, but that at 67.8 MHz becomes one major signal. Such splitting comes

from the quadrupolar interaction. By computer simulation, the quadrupolar coupling constant e^2qQ/h was determined to be 8.55 MHz. This value is much larger than that for the amide ^{14}N nitrogen nucleus (1.11 MHz). It is seen that the NMR spectra depend strongly on the measurement frequency because the quadrupolar effect depends on the measurement frequency, and the broadening of the ^{17}O NMR signal is further increased by the quadrupolar effect as the measurement frequency is decreased. Thus, it is clear that high-frequency measurements are needed for quadrupolar nuclei such as ^{17}O .

Figure 8 shows 67.8 MHz static ^{17}O CP NMR spectra of PG I, PG II, GlyGly, and GlyGly·HNO₃ (points), compared with the computer simulations (continuous lines). The ^{17}O NMR parameters of PG I, PG II, GlyGly, and GlyGly·HNO₃ obtained by computer simulations are shown in Table 3. From these results, the δ_{11} , δ_{22} , and δ_{33} values of the samples were found to change from 546 to 574 ppm, 382 to 425 ppm, and -132 to -101 ppm, respectively. The magnitude of the chemical shift change is much larger than that of the carbonyl

Figure 8 ^{17}O 67.8 MHz CP static NMR spectra of GlyGly·HNO₃ (a), GlyGly (b), PG I (c), and PG II (d), together with theoretically simulated spectra

Table 3 Determined ^{17}O NMR Parameters of Solid Peptides and Polypeptides Containing a Gly Residue

Sample	e^2qQ/h (MHz)	η_Q	Chemical shift tensor (ppm)						Angle Δ^a (deg)		
			δ_{11}	δ_{22}	δ_{33}	δ_{iso}	$\Delta\delta^b$	η^c	α	β	γ
<i>Polypeptides</i>											
PG II	8.30	0.29	562	410	−108	288	396	0.38	92	89	−81
PG I	8.55	0.26	574	425	−101	299	400	0.37	100	91	−79
<i>Oligopeptides</i>											
GlyGly	8.55	0.45	546	382	−132	265	397	0.41	94	90	−87
GlyGly·HNO ₃	8.75	0.47	559	408	−127	280	407	0.37	94	89	−81

^aAngle Δ indicates the Euler angles between the principal axes of the quadrupolar tensor and the chemical shift tensor.

^b $\Delta\delta = \delta_{\text{iso}} - \delta_{33}$.

^c $\eta = (\delta_{11} - \delta_{22})/\Delta\delta$.

^{13}C and amide ^{15}N chemical shift. Every $\Delta\delta$ defined by $\Delta\delta = \delta_{33} - \delta_{\text{iso}}$, is about 400 ppm, which is much larger than that of the carbonyl ^{13}C and amide ^{15}N chemical shifts by about 170, 100 ppm, respectively. Every η value, defined by $\eta = (\delta_{22} - \delta_{11})/\Delta\delta$, is roughly 0.4. These values are common to the carbonyl oxygen in peptides. Although the chemical shift tensor is axially symmetric ($\delta_{11} = \delta_{22}$) for the case of the carbonyl oxygen of L-Ala as reported by Fiat and co-workers,^{45,46} the chemical shift tensor of the carbonyl oxygen in the peptides considered here is not axially symmetric.

The e^2qQ/h values change from 8.30 to 8.75 MHz. These values are larger than the e^2qQ/h value of χ for L-leucine, which is 8.0 MHz at 190 K.⁴⁶ The η_Q values of polypeptides such as PG I and II are 0.26 and 0.29, and the η_Q values of oligopeptides such as GlyGly and GlyGly-HNO₃ are 0.45 and 0.47, respectively. The difference may come from a difference in molecular packing between them. Further, it is found that the principal axis of the quadrupolar tensor and the principal axis of the ^{17}O chemical shielding tensor for the carbonyl oxygen of the peptides and polypeptides are not coincident with each other. From these experimental results it can be said that each of the above NMR parameters is strongly influenced by the electronic structure of molecules.

So far, there has been little study aimed at determining the direction of the principal axes of the electric field gradient tensor and the chemical shielding of carbonyl oxygen of peptides and polypeptides from NMR experiments. The direction of the principal axes of the chemical shielding of the carbonyl oxygen of peptides and polypeptides has been calculated using FPT-MNDO-PM3 methods. It was found that the σ_{22} component lies approximately along the C=O bond, the σ_{11} component is aligned in the direction perpendicular to the C=O bond on the peptide plane, and σ_{33} which is the most shielded component is aligned in the direction perpendicular to the peptide plane. In the case of the electric field gradient tensor of the carbonyl oxygen, it was shown that the V_{22} component lies approximately along the C=O bond, the V_{33} component is aligned in the direction perpendicular to the C=O bond on the peptide plane, and the V_{11} component is aligned in the direction perpendicular to the peptide plane. These results show that the largest component V_{33} of the electric field gradient lies along the molecular chain direction. The relationship between the electric field gradient tensor and the chemical shielding obtained by this calculation agree with the experimental results.

The plot of the observed e^2qQ/h values vs. the hydrogen bond length shows that the e^2qQ/h values decrease linearly

with a decrease in the hydrogen-bond length ($R_{\text{N-O}}$) (in Å) as expressed by e^2qQ/h (MHz) = 5.15 + 1.16 $R_{\text{N-O}}$. This shows that the decrease of the hydrogen-bond length leads to a decrease in electric gradient (q). The value of q is very sensitive to the hydrogen-bond-length change. From this relationship it is apparent that the hydrogen-bond length can be determined by the observation of the e^2qQ/h value. The plot of the observed isotropic ^{17}O chemical shift values (δ_{iso}) against the hydrogen-bond length ($R_{\text{N-O}}$) shows that the δ_{iso} values in both peptides and polypeptides move upfield with a decrease in the hydrogen-bond length ($R_{\text{N-O}}$). The plot of the observed principal values of ^{17}O chemical shifts against the hydrogen-bond length ($R_{\text{N-O}}$) also shows every principal value in both the peptides and polypeptides and moves to low frequency with a decrease in the hydrogen-bond length ($R_{\text{N-O}}$).

From these experimental findings, it is clear that ^{17}O NMR spectroscopy will become a powerful tool for elucidating the hydrogen-bonding structure in solid peptides and polypeptides.

1 INTRODUCTION

1.1 Biomineralization: Background and Significance

Biomineralization, defined as the organized deposition of inorganic materials in the cellular or extracellular matrix, may be as simple a process as the formation of an iron oxide crystal in the vesicle of a magnetobacterium, or as complex a process as the formation of the intricate calcium carbonate and calcium phosphate structures found in marine coccoliths, invertebrate shells, vertebrate skeletons and teeth. The phenomenon of biomineralization has attracted a great deal of attention recently from the materials science community, which seeks to understand the way in which inorganic biological composites are synthesized and processed in nature.^{1–8}

An extremely important problem in the field of biomineralization is understanding the manner in which mineral deposition is controlled *in vivo*. The crystal engineering processes necessary to achieve the controlled deposition of minerals at physiological temperatures and in aqueous solutions are directly provided by proteins in most known examples.^{7,9–17} In particular, the deposition of minerals in most hard tissues in higher organisms is controlled by a class of unusually acidic, non-collagenous proteins and glycoproteins.^{9,10,17,21–28} These acidic proteins typically comprise only about 1% of the mass of the organic matrix, and are frequently found sandwiched between crystal surfaces and major framework molecules like collagen or chitin. They are rich in acidic amino acids including aspartic and glutamic acid, and contain large numbers of phosphorylated amino acids, especially phosphoserine.

In the specific case of hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$), the principal mineral component of bone and dental enamel, extra-cellular, acidic, non-collagenous proteins include apatite nucleators like bone sialoprotein, osteonectin, and dentin phosphoryn, while osteocalcin, osteopontin, and salivary statherin inhibit apatite formation and growth. In some cases (e.g.,

osteonectin, bone sialoprotein, and dentin phosphoryn) apatite formation is inhibited at high protein concentration while nucleation of apatite occurs at low protein concentration.

Substantial progress has been made in recent years in characterizing, at the macroscopic level, the structural properties of biological composites,^{1,18–20} but there is still a significant gap in our understanding of the molecular recognition processes underlying acidic protein-calcium composite interactions. In particular, while protein model structures have been proposed which hypothesize the involvement of protein secondary structure motifs for presentation of carboxylate residues,^{10,13,26,28,29} the lack of high resolution structural data for proteins on surfaces precluded any molecular structure vs. function studies.

The acquisition of molecular-level structural information for proteins on surfaces is not only important to the field of biomineralization but has broad applicability in a number of important fields. For example, there is currently a great deal of effort in the fields of drug delivery, implant design, tissue engineering, and diagnostics directed toward developing polymeric surfaces for immobilization and controlled release of peptides and proteins. Detailed structural information about proteins bound to material surfaces will provide important new design criteria from the perspective of peptide/protein structure, dynamics, and assembly at polymeric biomaterial surfaces.

1.2 The Role of Protein-Crystal Interactions in Biomineralization

Understanding the function of a biomineralization protein requires that the secondary and tertiary structure of the molecule be defined within its biological context, i.e. the protein in contact with the crystal. In addition, the precise nature of the interactions between the protein and the crystal which underlie the recognition process must be understood. This requires a knowledge of the contacts formed between the amino acid side chains of the protein and the ions in the crystal faces. The involvement of water molecules in these interactions must be understood as well.

Current investigations of protein-mineral interactions are commonly conducted with techniques that characterize the macroscopic behavior of proteins in the presence of mineral crystals. Equilibrium properties such as protein-crystal binding constants are derived via adsorption isotherm measurements, where data are analyzed usually by assuming a simple Langmuir model of protein adsorption onto the crystal faces. But the most commonly-used approach for determining protein-crystal interactions *in vitro* are kinetic experiments in which a small amount of protein is dissolved in a saturated solution of a particular inorganic salt and the time required for crystals to form is compared to a control solution in which no protein is present. Assays also exist for determining selective binding of a particular crystal face by a protein as well as oriented nucleation of crystals in the presence of acidic proteins.³⁰

However, to move beyond macroscopic aspects of protein-crystal interactions, what is clearly needed are high resolution spectroscopic methods that can provide information about the atomic level structure of the protein on the crystal face, under physical conditions that are biologically relevant (physiological levels of hydration and pH). Information about the secondary structural motifs that occur in the adsorbed protein together with information on the exposure of protein

side chains to the crystal face, may lead to an understanding of how particular proteins promote or inhibit nucleation. Analytical techniques currently used to probe protein-crystal interactions at the atomic and molecular levels and the advantages that solid state NMR bring to the field will be briefly reviewed in the next section.

2 NMR STRATEGIES FOR STUDYING SURFACE-ADSORBED PROTEINS

The lack of high resolution structural data for proteins on surfaces is the result of a lack of high resolution structural methods that can be brought to bear on relevant problems. The conventional methods of high resolution structural biology, X-ray crystallography and solution nuclear magnetic resonance (NMR) spectroscopy have provided information on a few biomineralization proteins in the pure crystalline and solution states,^{31–33} but both techniques are severely limited in their abilities to elucidate the structures of proteins on biomineral surfaces. Although traditional surface science methods like photo-electron spectroscopy and NEXAFS have provided important information on protein adsorbed onto planar surfaces, and, in particular, may be used to characterize the degree of long range ordering in systems of adsorbed proteins on polymer surfaces as well as average structural properties, these techniques have yet to provide detailed atomic-level structural information for surface-adsorbed proteins. In addition surface diffraction methods and many optical techniques are not applicable to proteins adsorbed onto porous surfaces (e.g., porous plastics) or to other surfaces which preclude long-range ordering.

To fully appreciate the utility of solid state NMR in the study of protein structure at biomaterial interfaces, it is first important to recognize the dual nature of the protein-surface problem. There is first the familiar structural aspect, alluded to briefly in the prior section, which includes defining the secondary and tertiary structures of the adsorbed protein and by implication any structural changes which occur upon binding to the surface. The structure and chemical composition of the crystal surface in contact with the protein side chains must also be understood. In addition, a less familiar but no less important aspect is the dynamics of the adsorbed protein. It is desirable that the protein be observed on the surface under biologically relevant conditions, i.e., fully hydrated. Dehydration of the sample may alter not only the structure of the protein from its biologically relevant form but may quench the dynamics of the protein on the surface. Here we refer to both whole-molecule dynamics describing the protein's rigid body kinematics on the surface and to internal dynamics wherein the protein's conformation may be labile on the NMR time scale. In the following section we will review how solid state NMR can be used to probe both molecular structure and dynamics on surfaces.

2.1 NMR Structural Methods for the Study of Protein Structure at Biomaterial Interfaces

Solid state NMR has long been used to identify and characterize the structures of small organic molecules adsorbed onto catalytic surfaces,^{34–36} argon matrices,³⁷ and silica surfaces.^{38–40} There similarly exist a number of solid state

NMR pulse techniques capable in principle of reporting the structures of surface-adsorbed proteins. The most straightforward approach is to evaluate the secondary structure of surface-adsorbed proteins from the chemical shifts of ^{13}C spins located in the protein backbone. This approach basically exploits the fact that the isotropic chemical shifts of the backbone carbonyl, α , and β ^{13}C spins of each amino acid residue are to varying extents sensitive to the local secondary structure of the protein. Although recent work by Oldfield and coworkers has placed structural interpretation of isotropic ^{13}C chemical shifts of proteins on a quantitative basis,^{41–43} in the past analyses of structures using chemical shift data have been applied empirically, i.e., by comparing experimentally observed ^{13}C chemical shifts for backbone ^{13}C spins to a large body of data, derived via ^{13}C Cross Polarization/Magic Angle Spinning (CPMAS) experiments from polypeptides of known secondary structure in the condensed state. An excellent example of this type of analysis is the seminal work by Fernandez et al.⁴⁴ who studied the structures of polyglutamic acid and polylysine adsorbed to hydroxyapatite and silica using ^{13}C CPMAS. In addition to studies of the conformations of polypeptides on apatite and silica surfaces, ^{13}C MAS has been used to study the incorporation of carbonate ions in bone and synthetic apatites,⁴⁵ and ^{31}P MAS has been used to characterize the structures of various calcium phosphates found in biological systems.^{46–48}

Isotropic chemical shift data can be supplemented by quantitative structural data obtained via orientational constraints and/or distance/torsion angle constraints. The best examples that illustrate the use of orientational constraints and distance/torsion angle constraints come from the membrane protein literature. Structural data on membrane-associated proteins have been acquired by two general types of solid state NMR data: (1) orientational constraints, usually obtained from magnetic interaction tensors located in the backbone of proteins oriented in mono-domain lipid bilayers; and (2) distance and torsion angle constraints acquired from proteins associated with unaligned lipid vesicles. The former class of experiment requires the application of local field spectroscopy techniques (e.g., PISEMA) to oriented samples.⁴⁹ Although possible to achieve with lipids, there is no general analog in biomaterial interfaces to the mono-domain bilayer construct, so the orientational constraint approach has yet to be applied to biomaterials. Because distance and torsion angle constraints are generally acquired from unoriented samples via homo- and heteronuclear dipolar recoupling experiments, this approach shows the greatest promise in studies of surface-adsorbed biopolymers.

There are a number of dipolar recoupling experiments currently used to address a variety of problems in the material and biological sciences. No attempt will be made here to comprehensively cover all the alternative methods, their relative advantages and disadvantages. The reader is referred to general review articles on the subject of dipolar recoupling for more extensive treatments of dipolar recoupling.^{50,51} The following discussion is provided simply to clarify some general properties of dipolar recoupling sequence referred to in descriptions of studies of surface-adsorbed proteins.

Solid state NMR spectra of spin 1/2 nuclei are dominated by two magnetic interactions, the chemical shift anisotropy (CSA) and the direct nuclear dipole-dipole interaction (Figure 1). As discussed above, the former interaction is valuable as a qualitative probe of protein structure. The dipole-dipole interaction

Figure 1 The dipolar coupling tensor is a uniaxial tensor. The principal axis frame of this dipolar tensor has a z axis parallel to the internuclear vector. The dipolar coupling is proportional to the inverse cube of the internuclear distance ($1/r^3$), and the second order Legendre polynomial $(3/2)\cos^2\theta - (1/2)$, where θ is the angle between the internuclear vector and the magnetic field. The solid state NMR spectrum of a pair of dipolar-coupled spin 1/2 nuclei with negligible CSA's should be a Pake powder pattern, from which the dipolar coupling constant may be easily extracted. However, if the coupled spin 1/2 nuclei have CSA's much larger than the dipolar coupling it will be difficult to extract the dipolar coupling constant from the NMR powder spectrum. The figure shows the powder spectrum of two dipolar coupled ^{13}C spins, each with a CSA on the order of 20 kHz; and with dipolar coupling of 500 Hz, corresponding to a ^{13}C pair separated by 2.5 Å. The spectrum is clearly dominated by the CSA and it is very difficult to discern the presence of a dipolar coupling in the spectral data

has a straightforward structural interpretation because the dipolar coupling constant is proportional to the inverse cube of the internuclear distance. However, in many systems composed of coupled spin 1/2 nuclei, the magnitude of the CSA may exceed the magnitude of the dipole-dipole interaction. For example, for two sp^2 hybridized, directly bonded ^{13}C spins the CSA's may approach 200 ppm, corresponding to over 20 000 Hz in a 9.4 Tesla magnetic field. On the other hand, the dipole-dipole interaction for this directly bonded spin pair will not exceed 2300 Hz, and may be even smaller for non-bonded ^{13}C spins. Therefore the dipolar coupling constant may not be easily discerned in spectral data when the CSA exceeds the dipolar interactions by orders of magnitude so it is necessary to use NMR methods which suppress one of these interactions thus enabling straightforward detection of the other.

In the late 1960s NMR coherent averaging experiments were introduced to remove the dipolar coupling between spin 1/2 nuclei (^{19}F , ^1H , etc.) in crystalline solids, while simultaneously preserving the chemical shift anisotropy (CSA).^{52,53} The spin dynamics that underlie these experiments have been thoroughly quantified with Average Hamiltonian Theory (AHT).^{54,55} Basically, homonuclear dipolar decoupling sequences like WHH-4,⁵³ MREV-8,⁵⁶ BR-24,⁵⁷ MSHOT-3⁵⁸ etc. exploit the different transformational properties of the chemical shift anisotropy (CSA) and the dipolar interaction in spin space to remove the homonuclear dipolar interaction while preserving a scaled CSA.

Physical rotation of the sample (i.e., Magic Angle Spinning,⁵⁹ MAS) coherently averages spatial parts spin interaction Hamiltonian that transform as second rank tensors. However, both the dipolar and the chemical shift Hamiltonians transform as second rank tensors in Cartesian space, so MAS removes

the effect of both interactions from solid-state NMR spectra. The objective of dipolar recoupling is to use MAS and radio frequency (rf) irradiation in synchrony, with the ultimate objective of suppressing the chemical shift while preserving the dipolar coupling. Because information on internuclear distances can be recovered using dipolar recoupling techniques, these pulse sequences are widely used in structural studies of molecular solids.

The two dipolar recoupling pulse sequences that will be discussed in the context of structural studies of proteins adsorbed at biomaterial interfaces are the heteronuclear recoupling experiment Rotational Echo Double Resonance (REDOR) and the homonuclear recoupling experiment Dipolar Recoupling with a Windowless Sequence⁶⁰ (DRAWS). REDOR, developed by Schaefer and coworkers has been reviewed elsewhere.⁶¹ We confine our remarks to stating that in studies of surface-adsorbed biopolymers REDOR has a number of uses including: (1) Direct characterization of the surface, as was done by Pan⁶² who used ^{31}P - ^{19}F REDOR to study the distribution of ^{19}F in fluoroapatite; (2) ^{13}C - ^{15}N REDOR to confirm helical secondary structures in surface-adsorbed proteins by measuring hydrogen bond lengths between the ^{13}C carbonyl spin of the i residue to the ^{15}N amide spin of the $i + 4$ residue; and (3) probing dipolar interactions from ^{13}C and ^{15}N spins in protein side chains to NMR-active spins in the surface, ^{31}P spins in hydroxyapatite and ^{19}F spins in fluoropolymers, for example.

DRAWS is well suited to measuring distances between backbone carbonyl carbons in peptides and proteins.⁶³⁻⁶⁶ Dipolar couplings of less than 40 Hz between carbonyl ^{13}C spins have been detected in biopolymers at high magnetic fields,⁶⁷⁻⁷⁰ attesting to the ability of DRAWS to suppress large CSAs and at the same time detect small dipolar couplings between non-bonded ^{13}C spins. Figure 2 shows three forms of the DRAWS dipolar recoupling pulse sequence. In the DRAWS experiment, the unit pulse cycle (Figure 2a) is applied synchronously with the sample spinning and thus the duration of the unit cycle is exactly equal to one rotor period τ_{rotor} . The DRAWS experiment, which utilizes a four step supercycle, shown in Figure 2(a), is commonly employed in the context of a CPMAS experiment, see Figure 2(a). The basic strategy is to detect the amplitude of transverse magnetization that remains after an integral number of DRAWS super-cycles. Repeating this measurement as a function of the number of DRAWS supercycles results in a "dephasing" curve (Figure 3). Simulation of this dephasing curve results in a value for the internuclear distance.

The DRAWS dephasing curve is a useful measurement for determining protein secondary structure because, as shown in Figure 3, the carbonyl-carbonyl distance is directly related to the Ramachandran torsion angle φ . Therefore, using DRAWS distance measurements, the torsion angle φ may be determined at several positions in a peptide in a model-independent fashion. An example of a DRAWS experiment applied to a crystalline tripeptide alanyl-glycylglycine (AGG), labeled at both carbonyl positions with ^{13}C , is shown in Figure 4. Agreement with the crystallographically determined φ of -83° is excellent. Additionally, DRAWS can also measure conformational heterogeneity since the dipolar recoupling efficiency is independent of any correlation between chemical shift and peptide secondary structure. This allows the determination of the distribution of peptide conformers in a given sample.

Figure 2 In most dipolar recoupling pulse sequences, pulsed irradiations are applied synchronously with the sample rotation. In DRAWS, the eight 360° pulses (alternating Y and $-Y$ phases) and two ninety degree pulses (X phases) that constitute the unit pulse cycle (R) are applied within a single period of the rotor (τ_{rotor}). (a) The unit pulse cycle for DRAWS (Dipolar Recoupling with a Windowless Sequence) is supercycled as RRRR, where $\bar{R}$ indicates a unit cycle phase-shifted by 180° . (b) DRAWS applied in the context of a CPMAS experiment. (c) Pulse Sequence for Doubled Quantum-filtered DRAWS. (d) Two dimensional pulse sequence for double quantum DRAWS (DQDRAWS)

DRAWS dephasing curve data may be difficult to quantify in terms of an internuclear distance if a large background signal occurs from ^{13}C spins at natural abundance. The ^{13}C background arises from portions of the protein that are not enriched with ^{13}C or may come from the surface itself if the mineral contains carbon (e.g., calcite) or if the mineral contains organic impurities (e.g., carbonate incorporated into apatite crystals). In such cases NMR signals arising from dipolar coupled spin pairs are separated from the natural abundance signal, which arises mainly from isolated spins, by filtering the DRAWS signal through a double quantum state. The preparation of double quantum coherence using DRAWS

dipolar recoupling is called DQDRAWS. The DQDRAWS filtering experiment is shown in Figure 2(c). Applying a DRAWS pulse sequence for a preparation time τ (typically 3–6 ms for carbonyl ^{13}C spins in the backbone of a surface-adsorbed protein) generates dipolar-correlated spin coherence (also called anti-phase magnetization). Applying a 90° pulse then generates double quantum coherence. In the double quantum buildup experiment, this coherence is immediately transferred back to anti-phase magnetization by a second 90° pulse and then to observable magnetization by reapplying the DRAWS mixing sequence for the same amount of time. The buildup of double quantum coherence is then monitored

Figure 3 Simulated DRAWS decay curves for dipolar-coupled ^{13}C - ^{13}C carbonyl spin pairs in the backbone of a polypeptide. The carbonyl-carbonyl distance is directly related to the Ramachandran angle φ

Figure 4 Experimental DRAWS dipolar dephasing curve obtained for the doubly carbonyl ^{13}C labeled crystalline tri-peptide alanyl-glycylglycine (AGG). The solid line is the simulation assuming a Ramachandran angle of -84°

as a function of the DRAWS mixing time to determine dipolar couplings and hence the inter-nuclear distance. As in the simple DRAWS experiment, the DQDRAWS filtering experiment can quantify the carbonyl-carbonyl distance and hence the Ramachandran angle φ .

Direct detection of a double quantum coherent state results in a simultaneous measurement of the (φ, ψ) Ramachandran angles.^{64,71} As in other multiple quantum experiments, a double quantum state is detected via a two dimensional

experiment, the pulse sequence is shown in Figure 2(d). In the 2-dimensional DQDRAWS experiment, the DRAWS pulse sequence is again applied for a preparation time τ to generate the antiphase state. After the magnetization is transferred to the double quantum state by a 90° pulse it is allowed to evolve under the chemical shift and dipolar interactions for a time t_1 . The magnetization is then transferred back to observable by a second 90° pulse and reapplying the DRAWS mixing sequence for the same amount of time. Monitoring the free induction decay (FID) during the detection time t_2 as a function of double quantum evolution time t_1 yields a two dimensional interferogram. Two dimensional Fourier transformation of the time domain data followed by projection onto the ω_1 axis (i.e. the double quantum frequency axis) yields the double quantum spectrum, see Figure 5. The double quantum spectrum consists of a “fundamental” frequency, which occurs at the sum of the isotropic chemical shift frequencies of the coupled ^{13}C spins, together with side bands at integral multiples of the spinning frequency. The double quantum spinning side band intensities are dependent on the principal values of the *sum* chemical shift tensor. Because the individual chemical shift tensors add as second order tensors, the sum tensor is sensitive to the mutual orientation of the principal axis systems of the CSA tensors of the coupled ^{13}C spins.

Since carbonyl carbons in peptides possess highly anisotropic CSAs, they are particularly sensitive to the DQDRAWS approach. The relative orientations of the carbonyl carbon CSAs to the peptide amide bonds are well-studied,⁷² and thus the torsion angles (φ, ψ) can be extracted by simulating the DQ spectrum. Determining (φ, ψ) with this level of accuracy not only yields secondary structure, but also gives some indication of helical pitch or twist and long range order.

Figure 5 Simulated and experimental projections of the two dimensional double quantum DRAWS (DQDRAWS) spectra of the doubly carbonyl ^{13}C labeled crystalline tri-peptide alanyl-glycylglycine (AGG). The simulation assumes $\varphi = -83^\circ$ and $\psi = 169^\circ$

The interaction between two nuclear magnetic dipoles, the interaction between the nuclear quadrupole moment and surrounding electric field gradients, and the chemical shift, are inherently tensorial quantities. In addition, these interactions detectable by NMR have sufficient anisotropy to dominate the solid state NMR spectral line shape. If internal motions modulate the orientation of magnetic interaction tensors relative to the static magnetic field direction, the solid state NMR line shape will be averaged in a way that reflects both the amplitude and the time scale of the internal motions. In addition, the relaxation of the nuclear system will be described by the time-dependent part of the spin interaction Hamiltonian. For these reasons the dynamic properties of solid polymers are frequently probed through measurements of NMR relaxation and line shapes.

Solid state NMR studies of polymer dynamics constitute an extensive literature, which cannot be summarized here in any thorough way. However, it is useful to briefly review some of the important NMR methods used in the past to characterize polymer dynamics, including surface-adsorbed polymers, in order to appreciate how these methods may or may not suffice to characterize surfaced-adsorbed proteins.

The most extensive class of polymers studied to date by solid state NMR methods are synthetic, organic polymers common examples being polystyrene,⁷³ polycarbonate,^{74–76} polystyrene–polybutadiene blends,⁷⁷ poly(ethylene-terephthalate),^{78,79} to name just a very few. In addition there are numerous reports on liquid crystal polymers,^{80,81} polymers tethered to silica surfaces,³⁹ and polylysine and polyglutamic adsorbed to silica and hydroxyapatite surfaces.⁴⁴ In the case of hydrocarbon-based polymers the NMR dynamic probes are ¹³C relaxation and line shape studies, proton relaxation and spin diffusion studies. In cases where protons can be replaced by deuterium, deuterium line shape and relaxation studies may be used to probe polymer motions. Because synthetic polymers are composed of regularly repeating, largely identical subunits, isotopic enrichment usually cannot be performed in a site selective manner. This means that NMR studies of polymer dynamics reflect motions that are associated with a repeating unit, or a part of the repeating unit.

Many of the problems and questions in biomineralization are similar to the structure/function issues familiar in structural biology and concentrate on specific domains within the protein: e.g., what is the identity, structure and dynamics of the mineral binding surface of the protein, what is the relationship of this binding domain to the rest of the protein, and how are the structure and dynamics of this domain related to the function? This latter question can only be answered if the orientation of the protein relative to the surface is known. These questions can only be addressed by studying the NMR line shapes and

3 A SOLID-STATE NMR STUDY OF SALIVARY STATHERIN ADSORBED ONTO HYDROXYAPATITE (HAP) CRYSTALS

Salivary statherin is a particularly well studied acidic phosphoprotein that inhibits the nucleation and growth of calcium phosphate minerals in the oral environment, and acts as a boundary lubricant.⁸²⁻⁸⁷ The N-terminus of statherin is highly charged, with the first five amino acids containing one aspartic acid, two phosphorylated serines, and two glutamic acids that have been shown to be important in the recognition of HAP⁸³ (Figure 6). A solution NMR study of statherin,⁸⁷ acquired in a water/TFE solvent mixture, found the N-terminus to be alpha helical and the C-terminus was judged to be a 3_{10} helix, although the relative paucity of NOE's in the C-terminus was interpreted as indicating non-rigidity. Recent solid state NMR studies have shown that the N-terminal 15 amino acid peptide derived from statherin (called SN-15), which is believed to constitute the bulk of the HAP binding site, is partly helical on the HAP surface.⁸⁸ Also, while the N-terminal 3-6 amino acids are immobilized on the surface, the remaining portion of the peptide toward the C-terminus show increased mobility.⁸⁹

However, to conclusively define the structure of the HAP-binding domain, the full-length protein must be studied on the mineral surface. In this section, we show how solid state NMR techniques have been applied to full length phosphorylated statherin on the hydroxyapatite crystal surface to characterize the high-resolution structure and dynamics of the N-terminal binding domain under hydrated and lyophilized conditions.

Site-specific isotopic labeling of statherin allowed structural determinations to be made unambiguously using the dipolar recoupling techniques DQDRAWS^{90,91} and REDOR. DQDRAWS, a double-quantum variant of the DRAWS homonuclear recoupling technique, was applied to measure the distance between adjacent backbone carbonyl carbons and thus yield model-free determination of the backbone torsion angle φ . Determination of individual torsion angles yields insights into local secondary structure as well as structural heterogeneity. Typically α -helices are indicated by torsion angle values in the range of -45° to -80° with a mean of -63° (Figure 7). The average values of β -sheets are somewhat larger, varying from -80° to -150° with a mean of

Figure 6 The primary sequence of the 43 amino acid protein salivary statherin and a possible structure based on solution and solid state NMR data

Figure 7 The carbonyl-carbonyl distance in the backbone of a polypeptide for various secondary structure motifs

–130°. REDOR, a heteronuclear recoupling technique, was used to measure the distance between the backbone carbonyl carbon and the backbone nitrogen involved in the hydrogen bond of a putative α -helical domain. This measurement is very sensitive to global secondary structure since theoretical distances expected for classical secondary structures vary from 4.2 Å for an α -helix to 10.6 Å for a β -sheet. Although isotropic chemical shifts of proteins can give qualitative indications of secondary structure in homogeneous systems, their values can be influenced by the bulk magnetic susceptibility of the support in heterogeneous systems. This makes them unreliable for structural determination in proteins closely associated with or adsorbed on inorganic surfaces such as HAP. Solid state NMR of ^{13}C nuclei is also very sensitive to dynamics, which can be probed over several order of magnitude by measuring chemical shift anisotropies (CSAs), relaxation constants including carbon T_1 's and $T_{1\rho}$'s, and proton $T_{1\rho}$'s.

The structure and dynamics of salivary statherin were analyzed at the pS₂, pS₃, F₇, L₈, I₁₁ and G₁₂ residues. Pairs of backbone carbonyl carbons were enriched at the pS₂pS₃, F₇L₈, and I₁₁G₁₂ positions in separate samples and probed using DRAWS and DQDRAWS. A ^{13}C enriched carbonyl carbon was introduced at the (i) position with an ^{15}N enriched amide nitrogen at the (i + 4) position in pS₃F₇ and L₈G₁₂ samples and probed using REDOR to verify the presence or absence of hydrogen bonding. The dipolar recoupling data for the pS₂pS₃ and pS₃F₇ samples are shown in Figure 8. All 5 samples were characterized using standard ^{13}C CPMAS and $T_{1\rho}$ relaxation sequences to measure any averaging of carbonyl carbon CSAs, cross polarization efficiencies, or relaxation due to the presence of motion. Measurements on all samples were performed under in situ conditions (i.e. buffered and hydrated) as well as after lyophilization. These results are summarized in Table 1.

Both the single torsion angle measurements and the distances between putative hydrogen bond donors and acceptors indicate the N-terminal 12 residues in statherin are in an α -helical conformation when adsorbed to HAP under biologically relevant conditions. Removal of water via lyophilization under low vacuum (i.e. 100 mTorr) results in loss of this structure in the highly acidic N-terminal 6 residues. The extension of the helix during lyophilization suggests a significant role for water in stabilizing the binding domain. Water may mediate the interaction of the acidic sidechains with the HAP surface. The α -helix has been previously suggested as a general structural mechanism for aligning acidic side-chain residues with HAP,⁹² either through lattice matching or through more general electrostatic complementarity. While our data support the presence of this secondary structure, they also point to the possible importance of water in HAP binding.

The dynamic properties of the immobilized protein are a critical aspect of molecular recognition at the

Figure 8 (a) REDOR dephasing curves for hydrated, surface adsorbed pS₃F₇ Statherin (◆), lyophilized, bound pS₃F₇ statherin (◇), and simulations for 4.2 Å (unbroken blue line), 5.2 Å (dashed red line) and a combination of 45% α -helix (4.2 Å) and 65% β -sheet (>8 Å) (unbroken red line). The hydrated pS₃F₇ distance across the hydrogen bond fits best to a distance of 4.3 Å, indicating that the region is well described by an ideal α -helix. Data for the lyophilized sample is best simulated by 5.2 Å or a combination of 35% α -helix and 65% β -sheet, indicating a loss in α -helical secondary structure upon lyophilization. (b) DQDRAWS buildup curves for hydrated, surface adsorbed pS₂pS₃ statherin (◆), lyophilized, bound pS₂pS₃ Statherin (◇), and simulations for ϕ torsion angles of –60° (unbroken blue line), –85° (dashed red line) and a combination of 45% α -helix (–57°) and 65% β -sheet (–120°) (unbroken red line). The increase in torsion angle on lyophilization correlates well with the loss of α -helical secondary structure

Table 1 Values for the anisotropy ($\Delta\sigma$) and asymmetry (η) of the CSA, average values of the torsion angle (φ), distance measurements across putative hydrogen bonds and ^{13}C $T_{1\rho}$ relaxation constants measured for indicated residues of salivary statherin bound to HAP in the presence and absence of water

Isotopic label	$\Delta\sigma$ (ppm)		η		φ /distance		$T_{1\rho}$ (ms)	
	Lyo.	Hyd.	Lyo.	Hyd.	Lyo.	Hyd.	Lyo.	Hyd.

protein-biomaterial interface, and relatedly to the function of proteins once adsorbed. Measurements of the dynamic properties of statherin in the presence and absence of water show a striking difference from the structural data. The ^{13}C $T_{1\rho}$ values remain largely unchanged for the phosphoserines, indicating little or no motion is present in both the lyophilized and hydrated states. However, the $T_{1\rho}$ relaxation constants are considerably shorter in the hydrated samples at the F₇, L₈, I₁₁ and G₁₂ positions, indicating motion on the kHz timescale when water is present. Figure 9 shows CPMAS spectra for each of the doubly carbon-labeled statherin

Figure 9 CPMAS spectra of (a) pS₂pS₃ Statherin bound to the surface and lyophilized, (b) hydrated, surface-adsorbed pS₂pS₃ Statherin (c) hydrated, surface-adsorbed F₇L₈ Statherin and (d) hydrated, surface-adsorbed I₁₁G₁₂ Statherin. Each hydrated spectrum is normalized to the natural abundance methyl region. The significant decrease in the carbonyl signal for the F₇L₈ and I₁₁G₁₂ hydrated spectra is indicative of molecular motion. $T_{1\rho}$ relaxation measurements support the interpretation of minimal mobility at the pS₂pS₃ region and increased mobility for the F₇L₈ and I₁₁G₁₂ regions

samples under hydrated conditions, normalized to the natural abundance methyl region to account for any differences in the amounts of bound protein. A representative spectrum of a lyophilized, surface bound sample labeled at the pS₂ and pS₃ positions is also shown for comparison. The significant loss in CP efficiency at the F₇, L₈, I₁₁ and G₁₂ positions in the hydrated samples is also characteristic of mobility. These measurements bracket the timescale of the motion in this region to 10^{-3} – 10^{-5} s. In contrast, the hydrated, surface bound pS₂pS₃ region does not display a loss in CP efficiency, indicating there is very little motion in that region on the timescale of the cross polarization experiment. The CSAs were found to narrow very little, with spans ($\Omega = |\sigma_{11} - \sigma_{33}|$) of approximately 140–150 ppm in the hydrated samples, as compared to 145–155 ppm for their lyophilized counterparts. The small change in the CSA under hydrated conditions indicates that the motion observed in the cross polarization experiments and supported by the $T_{1\rho}$ relaxation measurements somewhat restricted. Motion was observed in analogous regions for the isolated SN15 peptide, but significant narrowing of the CSA was observed at the C-terminal residues of the peptide (I₁₁ and G₁₂). The nearly unchanging CSA observed for the entire N-terminus of statherin indicates a different motional mode present in the full protein. The $T_{1\rho}$ relaxation parameters for both protein and peptide are nearly the same, which would support a motion of similar frequency, but different amplitude than that observed in the SN15 peptide. The change in mobility could be due to one of several factors, including motional limitations due to the larger size of the protein, stabilization of the peptide backbone by tertiary structure, or potentially due to more substantial protein interactions with the surface at the C-terminal end of full statherin.

To explore the latter possibility, the only negatively charged residue outside of the N-terminus was replaced with its uncharged counterpart (Glu₂₆ → Gln₂₆). This site-directed statherin mutant displayed a $T_{1\rho}$ value at I₁₁G₁₂ of 2.9 msec, identical to the $T_{1\rho}$ value at the same positions of the unmodified protein (2.5 ms) within experimental uncertainty. This indicates that Glu₂₆ is not involved in HAP recognition to an extent that prevents kHz frequency motions in the N-terminal region. The simplest explanation of the results is that either the larger size of full-length statherin or tertiary structural interaction is causing the lower amplitude dynamics compared to the isolated SN15 peptide, rather than being due to a different type of interaction with the HAP surface. However, the dynamics data could also be explained by more complicated models that do include protein interactions

Figure 10 Schematic model showing statherin interacting with the 001 face of HAP, with calcium ions in white and phosphoserines in purple. The protein colors represent backbone ^{13}C = O-enriched (red), ^{15}N -enriched (blue), and unenriched (yellow) residues. The REDOR-measured hydrogen bonding distances are indicated for the hydrated N-terminal binding domain, while the remaining portion of the protein (blue) is shown as a nondescript shape to indicate unknown surface adsorbed structure (hydrogen bonds in white). The strong interaction of the N-terminus through the immobile phosphoserines is indicated, and the more mobile, non-interacting C-terminus of the pentadecyl domain is shown oriented away from the HAP surface

with the surface outside of the N-terminal domain. It is clear, however, that both the protein and peptide are only loosely associating with HAP outside of the anionic N-terminal pentapeptide region. The pentapeptide sequence is a common motif in many bone and tooth-associated proteins. It is also a recognition sequence for phosphorylation. The importance of the phosphorylated serines in statherin in binding to HAP indicates a possible regulatory mechanism for multifunctional proteins, such as osteopontin, which are found to be important in regulating mineralization in some settings, but are found in other tissues as well.

A molecular model consistent with the current structural and dynamic studies is shown in Figure 10. The N-terminal domain from residues 2 to 12 is helical on the surface. The strong interaction of statherin with HAP is mediated by the acidic N-terminus, where two phosphoserines and three carboxylate-containing side-chains are located. The dynamics studies suggest that the remainder of the helix is much more weakly interacting with HAP. The more weakly interacting residues in this domain could be viewed as a flexible rod, with torsional motions increasing with increasing distance from the highly immobile N-terminal pentapeptide sequence. The presence of a highly mobile protein segment could explain functional observations made previously by others in the field. Moreno et al.⁹³ found that statherin inhibited secondary crystal growth at a higher level than that expected based on coverage size, assuming a fixed, globular protein. The mobility of statherin could allow it to effectively block more nucleation sites than a completely rigid protein. The mobility of statherin on the surface may also play a significant role in the lubricating properties of the protein. To adequately model the observed motions at the molecular level, further details of the surface bound tertiary structure and experimental elucidation of the side-chain interactions with HAP will be required to orient statherin at the surface. Solid-state NMR does provide a direct

route to this information, and we are currently probing the tertiary structure and the interactions of side chains with the surface to further elucidate binding mechanisms.

1 ASSIGNING HIGH RESOLUTION SPECTRA OF BIOLOGICAL SOLIDS

Numerous important proteins are not studied by X-ray or solution nuclear magnetic resonance methods because of size or insolubility. Solid-like systems, proteins for which the whole-body hydrodynamic tumbling is insignificant on the millisecond timescale, can be studied by high resolution solid state nuclear magnetic resonance (SSNMR), formulated as raw membranes or native multi-enzyme complexes, micelle-protein suspensions, frozen glasses, or hydrated microcrystals. One important application area of solid proteins is the study of cryogenically trapped species in proteins. Another is the problem of non-soluble misfolded systems; this field continues to increase in its medical and biophysical impact. Many of these systems have been extensively elucidated by SSNMR because of their insolubility, including the β -amyloid peptides.^{1,2} Another very important application area is the structural biology of intrinsic membrane proteins; these proteins are key players supervising cell–cell communication and making energy available to the cell. Exciting studies of membrane systems by solid state NMR are underway and partial structures at atomic detail are forthcoming for many fragments of membrane systems and fragments of insoluble proteins, including: gramicidin A,^{3,4} a fragment M2 of the acetylcholine receptor,⁵ phospholambin,⁶ aspartate chemotaxis receptor,⁷ viral fusion peptides,⁸ rhodopsin,⁹ and bacteriorhodopsin.¹⁰

Solid state NMR studies of these systems offer similar kinds of information as solution NMR studies offer for soluble proteins. For example the chemical structure, the conformation,

the conformational dynamics, and the pK_a values for ionizable residues are among the types of characterization that can be carried out. On the other hand, there are important differences between solid state and solution NMR, both technical and scientific. Principally the differences are related to the fact that all of the fine structure information (chemical, quadrupolar coupling, dipolar couplings) are anisotropic. While the anisotropy can be a source of spectral complexity and line broadening, these anisotropic interactions are also the principal source of structural and chemical information in a NMR spectrum. Dipolar couplings offer a direct probe of internuclear distances. Anisotropic shielding terms and quadrupolar splittings offer information on local electronic structure. All anisotropic interactions can in principle offer an angular constraint on a functional group with respect to an external coordinate system. Usually the nucleus has several local interactions (all tensorial). Some pulse sequences aim to isolate and measure one interaction. Other experiments depend on the sum of two interactions, and these allow one to probe the relative orientations of two anisotropic interactions and thereby potentially probe torsion angles. Any anisotropic interaction provides a basis for orientational labeling thereby offering an avenue for probing dynamics: hole burning recovery experiments, lineshape experiments and relaxation based experiments all typically operate on the basis of anisotropic local interactions and the effects of motion on the energy levels. The biophysical information provided through tensorial interactions is indeed very broad, and the need for a quantitative understanding of them is clear.

The impact of the anisotropy of these interactions for solution NMR is very different from that for solid state NMR. The tumbling of small molecules on a picosecond timescale or of macromolecules on a nanosecond timescale leads to narrowed spectra that report the weighted angular average of the values. The tumbling also leads to relaxation phenomena that are dominated by overall molecular tumbling; the relaxation rates are largely predictable from Stokes–Einstein type relations. Recent developments in solution NMR make additional creative use of the tensorial interactions. For example, small dipolar-based splittings for weakly macroscopically aligned samples can offer useful structural constraints (see **Liquid Crystalline Samples: Application to Macromolecular Structure Determination**). If two tensors of comparable size and spatial direction, but of opposite sign, dominate the local field, then the local field can be quite small, and therefore relaxation rates and linewidths are minimized for macromolecules (see **Transverse Relaxation-optimized NMR Spectroscopy with Biomacromolecular Structures in Solution**). Probably the future will bring ever more clever use of anisotropic interactions in solution NMR spectroscopy.

In contrast, for solids the anisotropy is manifest in the spectra. For single crystals, the anisotropy is studied through rotation plots, where the rotation of a sample leads to large changes in the NMR shift. This relation between functional group orientation and NMR frequency has formed the basis of structural studies of uniaxially aligned intrinsic membrane proteins by solid state NMR (see **Multiple-Resonance Multi-Dimensional Solid-State NMR of Proteins**). For powdered static solid samples the anisotropy results in inhomogeneously broadened lines wherein the resonance frequency is analytically related to the rotational orientation of the parent functional group. The experiments described in this review are

based on yet another scheme, magic angle spinning (MAS), in which polycrystalline solids are rotated mechanically at an axis of 55.7° with respect to the applied magnetic field. During MAS all first order interactions (i.e., interactions that are much weaker than the applied field) will refocus at the end of every full turn of the rotor. In this case the spectra contain a comb of narrow lines for each chemically distinct site, with a ‘center band’ at the isotropic shift and spinning sidebands flanking this center band, spaced by integral numbers of the rotation frequency. These spectra can, in favorable cases, exhibit resolution and sensitivity approaching that of solution NMR. On the other hand, the anisotropic interactions remain measurable or amenable to manipulations by the experimentalists. Since the tensor is not averaged by random molecular motion but rather by systematic magic angle spinning, powerful probes of dipolar couplings, of shielding anisotropy, of local torsional states and of local molecular motion on the microsecond and millisecond timescale are still available. Interactions that are comparable to or stronger than the spinning speed are sometimes probed through the amplitudes of the spinning sidebands, or equivalently through the dephasing and refocusing of the magnetization during each rotor period. Alternatively, weaker interactions can be probed through cumulative dephasing or evolution over several rotor periods when the RF pulses, synchronized with the rotor cycle, interfere with the formation of rotor echoes. Clever utilization of this fact has allowed experimentalists to select the terms in the Hamiltonian that should remain active and quench those that are not wanted.

For solid samples, relaxation is driven purely by local molecular motions; the lack of overall molecular tumbling has significant potential advantages for studies of conformational dynamics by NMR. Changes in the orientation of a functional group often result in very large changes in frequency, typically much larger than they would in solution. Although the relaxation rates are frank probes of local conformational motions, and sound theoretical tools exist for predicting relaxation rates from motional models, interpretation of experimental relaxation rates for solid proteins is nonetheless a muddy topic, needing much development.

MAS NMR has been used for the purpose of confirming the presence of a chemical species in an enzyme active site, or measurement of an internuclear distance to confirm the conformation of an important functional group in a protein. Site-specific isotopic enrichment with ‘heteronuclei’ (^{13}C or ^{15}N) at strategically selected sites has been a key ingredient in most of these biophysical solid state NMR studies.¹¹ The use of engineered isotopes obviates the need for peak assignments and allows one to utilize one-dimensional broadband methods. Because the labeling site(s) must of course be selected in advance, experiments with site specific labels often test a specific hypothesis, involving a particular set of atoms of interest in the macromolecule. These methods are useful for focusing on specific ligands or domains in very large structures, for example in the case of taxol conformational studies on tubulin,¹² or the case of chemotaxis receptors.⁷ The strength in many of these studies is the unique ability to probe a system under highly biologically relevant conditions or in a chemically unusual state, regardless of the intrinsic linewidth and dispersion; the weakness is the inefficient rate at which structural information is gathered.

Recently, efforts to study uniformly or extensively isotopically enriched biological solids including assignment of the

spectra have met with an encouraging level of success in several laboratories. The objectives in these experiments are to study simultaneously an entire protein or an entire domain of a protein, and probe such issues as conformation, dynamics and ligand binding. The use of uniform enrichment represents an important change in experimental planning; optimal conditions for resolving the hundreds of ^{13}C and ^{15}N lines must be found, and strategies are needed for determining peak assignments. These issues have been, to some degree, tackled in the recent past. Partial assignment of ^{13}C and ^{15}N resonances for protein solid state NMR spectra have recently been shown to be feasible for small globular proteins^{13,14} through multi-dimensional correlation of the backbone nitrogen and the side-chain $\text{C}\alpha$ and $\text{C}\beta$ isotropic shifts. Homonuclear ^{13}C shift correlation spectra during magic angle spinning was used to identify sidechains on the basis of isotropic carbon chemical shifts, while heteronuclear ^{15}N – ^{13}C chemical shift correlation spectra during magic angle spinning was used to provide site specific assignments for these spin systems. Thus far proton spectroscopy has not been extensively used in this context. Once site specific assignments are determined, a broad range of biophysical characterization can be carried out using solid state NMR. $^{13}\text{C}\alpha$ and $^{13}\text{C}\beta$ isotropic shifts provide information on the secondary structure context.^{15,16} The shifts are sensitive probes of ligand binding and can be used to locate the important cavities in the protein. It is possible that complete 3D structures of proteins will be soon determined using these spectra. It is likely that characterization of conformational changes, ionization states and proton transfer and other chemical reactions will be possible using these spectra. This review will attempt to offer a summary of the prospects for these studies, including some speculation about the near term future (Figure 1).

The chemical shift correlation experiments require the ability to ‘turn on’ and ‘turn off’ dipolar couplings during

Figure 1 Backbone $\text{C}\alpha$ –CO correlation spectra of microcrystalline BPTI, measured at 800 MHz as described in Ref.¹³. Many peaks were assignable based on 1-bond and 2-bond homonuclear correlations

a pulse sequence. During the indirect and direct detection periods, magic angle spinning and RF decoupling conditions can be combined such a way that the internuclear couplings are essentially ineffective and negligible. The linewidths typically seen in MAS spectra (0.5–2 ppm) indeed allow many residues to be resolved and assigned. On the other hand, during mixing periods the dipolar couplings can become effective for polarization transfer due to the use of other types of RF pulses that are synchronized with the rotor rotation. Advances in MAS based magnetization transfer allow for directed, highly efficient homonuclear (^{13}C – ^{13}C) or heteronuclear (^{13}C – ^{15}N) transfers during the mixing times.

The main ingredient providing narrow lines for measurement of chemical shifts during the detection periods is magic angle spinning. The selection of the spinning rate is important, and is typically in the range 5–30 kHz for applied field strengths in the range 400–800 MHz. In a practical sense it is crucial that the angle is set accurately (within 0.05°) for high field work, and is maintained stably. It is also crucial that the proteins survive long signal acquisition times in these conditions. Protein samples experience forces comparable to those in an ultracentrifuge, and care must be taken that the formulation of the sample (e.g., crystallinity) is not changed during the experiment. Furthermore, it is important that the large volumes of dry gas used in this protocol not accidentally dehydrate the sample. In order to achieve acceptable linewidths for ^{13}C or ^{15}N NMR peaks, strong proton decoupling must be applied throughout all direct and indirect detection periods; typically decoupling strengths of 80–125 kHz are used. If these MAS and proton decoupling techniques are applied, then linewidths of the order of 0.2–0.5 ppm can be expected for isolated spins in crystalline materials.

There are other central points influencing the quality of the spectra of uniformly isotopically enriched biological macromolecules, and therefore influencing the likelihood of succeeding in an assignment protocol. Of course, the applied field strength, homogeneity, and stability remain among the most important variables in the quality of any high resolution NMR spectrum. However, the need for high fields for proteins in solution is not fully analogous to the need for solid proteins. The linewidths and transverse relaxation rates for proteins in solution have a formal dependence upon molecular weight as governed by the Stokes–Einstein relation; this of course has no relevance for solid state samples. For solid state uniformly labeled samples, the most important reason that high field NMR improves spectra is related to internuclear homonuclear ^{13}C couplings, and the use of direct ^{13}C detection. Assuming that there is little inhomogeneous dispersion, homonuclear spin couplings can have a dominant effect on the linewidths of uniformly enriched materials. J values of 35 Hz for $^{13}\text{C}\alpha$ – $^{13}\text{C}\beta$ and 55 for Hz $^{13}\text{C}\alpha$ – ^{13}CO coupling are expected to add significant apparent width and there is substantial merit in refocusing these interactions to achieve a homogeneous underlying linewidth. Of course these splittings are fixed with respect to variations in the applied field, and have a more important effect on the resolution at low field than at high field. In solution NMR of uniformly labeled materials, ^{13}C shifts are often measured during constant time indirect evolution periods, thereby removing this source of broadening. Due to the relatively shorter expected dephasing times in solids, selective decoupling pulses have been proposed for removing these J couplings from indirect evolution periods of

solid state spectra.¹⁷ Such a technique is only recently under consideration, and will probably be very useful for indirect dimensions. No such remedy has been demonstrated for direct detection periods. For solid state ^{13}C NMR spectra, homonuclear dipolar couplings can also add significant linewidth. In this regard the selection of magic angle spinning speed is very important. ‘Rotational resonance’ conditions, conditions wherein spinning sidebands of one carbon spectrally overlap the center band or isotropic shift of a strongly coupled (directly bonded) neighboring site, must be avoided. When overlap of this type occurs, the spectra become much more congested, and dipolar interactions cause significant line broadening. For moderate applied magnetic field strengths, significant linewidth is added also when the peaks are close to, but not exactly at, a rotational resonance condition. Therefore very low and very high spinning speeds often offer the best linewidths. As stronger magnets are utilized, this effect becomes less important; at high fields, the rotational resonance conditions occur in more sharply defined ranges of speeds, whereas for lower field strengths the conditions are quite broad. Strongly coupled ^{13}C pairs with similar chemical shifts and large chemical anisotropy tensors, such as neighboring aromatic carbons, also exhibit a significant degree of dipolar linewidth during MAS experiments, which can resist even moderately high spinning speeds and applied field strengths. Thus the aromatic groups in uniformly enriched proteins present a specific spectroscopic challenge.

For some experiments, the homonuclear couplings, both J and D , can be removed or reduced through selective isotopic labeling. Labeling strategies¹⁸ involve use of 1,3- ^{13}C or 2- ^{13}C glycerol¹⁹ or 3- ^{13}C -pyruvate²⁰ media to derive ‘even-odd’ or ‘checkerboard’ labeling schemes. These approaches might have important impact for directly detected carbon spectra, especially for cases with small chemical shift differences in between neighboring nuclei such as aromatic systems and neighboring methylene groups.

Additional effects of applied field strength on the linewidth and resolution can be expected but are not well documented at present. An underlying apparently homogeneous linewidth would presumably be associated with the residual proton couplings during moderate proton decoupling irradiation, while other contributions to the transverse relaxation rate might be expected from fast-limit motions. It is expected that these sources of transverse relaxation would become less important with increasing field, but the extent of improvement is not yet well characterized.

Finally, the sample’s physical formulation is simply the most significant consideration; a structurally and physically homogeneous sample is required for high resolution multi-dimensional work, no matter what field strength is available. Benchmark linewidths have never been achieved using dehydrated or lyophilized materials. While crystalline materials satisfy this requirement they are probably not the only way in which this can be achieved. Raw biological membranes have shown very good linewidths in several cases. No matter what linewidth is achieved, of course the dispersion of the protein is equally important as the linewidth in determining the likelihood of resolving lines. This can be expected to be strongly influenced by the secondary structure content, by whether the protein is well folded or not, and by many other factors.

It is not possible to close this discussion of the achievements and benchmarks and likely future for assignment work by solid

state NMR without mentioning the expected effects of protein conformational change. Like the case for solution NMR, conformational exchange in proteins is expected to broaden the line and to reduce the efficiency of many of the polarization transfer sequences. Both effects are much more pronounced for proteins in the solid state; both effects involve a much broader range of timescales than they do for solution NMR. For a solid state protein, the conformation exchange causes a modulation in the frequency governed by the breadth of the anisotropic interaction; for solution NMR the effect mainly involves the difference in chemical shift. In solid state NMR experiments motions can also interfere with the two central tools for sharpening the spectra, namely MAS and proton decoupling. Thus motions on timescales from seconds to microseconds can contribute to chemical exchange, and the expected result is a reduced line intensity. The lack of peaks for many of the important lines is a 'half-empty cup'; the many opportunities, including lineshape analysis and relaxation rate measurements, for experimentally probing conformational exchange during biochemical function is a 'half-full cup'. Experimental control of the sample and thereby the motion is expected to be a very important tool in understanding these exchange effects. For example, variable temperature experiments or titration of the sample to control the rates and populations involved in the motion may serve as important throttles on the exchange effects. To the extent that the peaks can be recovered at lower temperatures or altered conditions, and the underlying spectroscopic constants can be determined, then one can hope that these interference effects could be useful for characterizing conformational exchange.

The restoration of dipolar couplings during MAS for the purpose of distance measurements has been accomplished in many ways. The effective average dipolar coupling for a spin pair undergoing MAS is zero, and no population transfer is expected after a full rotor period. Most methods to effect population transfer within the pair involve RF pulses with cycle times that are related to the spinning speed. For example, in one implementation, the specific CP sequence utilizes a condition in which the difference in RF field strength for the two spins is equal to the rotor frequency. In this case, the average Hamiltonian for the internuclear dipolar coupling, averaged over a full rotor period, can be shown to be non-zero. While these sequences have their historical origin in the study of site specific pairs of labels, most of them work well for detecting strongly coupled pairs such as directly bound pairs in uniformly labeled samples.

What sequences were actually used for population transfer during the mixing time of the chemical shift correlations of proteins? In some assignment efforts reported to date, adiabatic homonuclear transfer sequences at moderate field strengths were featured,¹⁴ such as dipolar recoupling enhancement through amplitude modulation (DREAM),²¹ an adiabatic version of the homonuclear rotary resonance (HORROR) condition, which involves rather mild RF field strengths conditions. Alternatively, homonuclear recoupling has been achieved using simpler sequences such as spin diffusion and RFDR sequences.¹³ The selection of these sequences rather than the many others in the literature partly reflects practical considerations of instrument stability, the ease of 'set-up' and minimization of RF strength and attendant sample heating. With respect to heteronuclear ^{13}C - ^{15}N correlation spectra, selective cross polarization has been most often used

for protein assignment.²²⁻²⁴ Transfer efficiencies of 25-50% on model systems and proteins have been reported. 3D ^{15}N - ^{13}C - ^{13}C correlation spectra have been reported for simple systems but not yet for large proteins.²⁵⁻²⁹

While the benchmarks for linewidths continue to drop, and the benchmarks for polarization transfer efficiency continue to rise, it is already clear that assignments of protein MAS spectra can be achieved, and that other aspects of the NMR studies such as structure determination and biophysical characterization are therefore ripe for pursuit.

2 EXPERIMENTAL STRUCTURAL CONSTRAINTS

With the recent accomplishments of partial assignments of several proteins, one issue lying ahead is the question of whether it is possible to solve the three-dimensional structure of a protein. Prospects for structure calculations based on distance and torsion constraints from solid state NMR experiments appear to be promising, although demonstrations are still at an early stage. It is useful to divide this process into characterization of secondary structure, determination of the fold and refinement to produce high quality structures. Many measurements are sensitive to backbone torsional states and can be used to characterize secondary structure. Chemical shift measurements are known to correlate with torsional states of the backbone.^{16,30} A variety of computational strategies have been developed to take advantage of the growing database of chemical shifts for proteins. Isotropic shifts can be analyzed using the chemical shift index, a well calibrated indicator of secondary structure, which is likely to work as well for microcrystalline proteins as it does for proteins in solution. Chemical shifts have been included in a refinement algorithm to effectively restrain the ϕ and ψ torsional angles and predict secondary structure with an accuracy of approximately 85%. Chemical shift surfaces could also be used to utilize the torsional information in the shift and shift anisotropy more quantitatively.³¹

Alternatively, the torsion angles in the backbone (or side chain) can be directly measured; many solid state NMR methods for torsion angle measurements have appeared recently.³²⁻³⁴ Heteronuclear local field spectroscopy is the underlying tool for most of these methods. In these experiments, the relative orientations of two tensors are measured in an unoriented sample. To probe X-Y bond torsions, one generates double quantum coherences for neighboring nuclei X and Y. Subsequently one probes the sum dipolar tensors for adjacent sites $D_{\text{P-X}} + D_{\text{B-Y}}$, using a dephasing pulse sequence that simultaneously excites both passively coupled spins P and B and simultaneously both dipolar couplings are re-introduced. The double quantum coherence for each crystallite will evolve under the sum of both local fields, and the angular relationship between the two dipolar tensors $D_{\text{P-X}}$ and $D_{\text{B-Y}}$ has a strong effect on the sum dipolar tensor. For example, if the dipolar tensors are collinear, the tensors are added 'in line', i.e., if for one particular crystal at one orientation the dipolar coupling for P-X is positive, then that for B-Y is also positive; more rapid dephasing is expected for each crystallite and broader dipolar tensors are expected. Alternatively, if the tensor orientations are at right angles to one another the shifts work in opposite directions and cancel each other; in this case a more slowly dephasing spin evolution and a narrower tensor is expected.

The relative orientation of the two tensors can also be probed without actually generating a multiple quantum coherence; if the dipolar dephasing for P–X and B–Y can be measured at separate times in the sequence, but if the two dephasing intervals are rotor synchronized, and if the evolution periods are incremented in a coordinated fashion, then the experiment will also probe the relative orientations of the two tensors. All of these separated local field based methods are expected to be well suited for uniformly enriched proteins. Backbone torsion angles could be measured with these methods; ϕ can be measured using the $^1\text{H}^{15}\text{N}^{13}\text{C}^1\text{H}$ spin system,³⁴ and ψ can be measured using $^{15}\text{N}^{13}\text{C}^{13}\text{C}^{15}\text{N}$ systems,³² thus providing another reliable method for recognition of secondary structures. Side chain torsion angles involving $^1\text{H}^{13}\text{C}^{13}\text{C}^1\text{H}$ spin systems can be similarly measured.³³ Although for many of these methods multiple conformers are expected to be compatible with the same spectra, distinct patterns are generally expected for α -helical or β -sheet conformations.

For tertiary structure determination, or fold definition, long range constraints serve a critical role. By far the most commonly used type of long range information for protein structure determination has been the distance measurement between nuclei from residues far separated in the primary sequence (more than five residues apart). Therefore we focus on the question of the number of potentially useful long range distance constraints in solid state NMR spectra of uniformly or extensively labeled systems.

What tertiary structural constraints can be measured in uniformly labeled systems? This important question is largely open at present. At first glance, it appears that the common nuclei in isotopically labeled proteins, ^1H , ^{15}N and ^{13}C , provide many opportunities for measuring long range distances. Poor spectral resolution and dense networks of multi-spin couplings, however, make the protons a complicated reservoir for measurement or for relaying structural information. This situation is likely to change in the near future; preliminary efforts for distance and torsion angle measurements based on direct detection of protons in extensively deuterated peptides look quite promising, and perhaps these nuclei will ultimately be an important component of a protein structural protocol.^{35,36} Carbon nuclei are numerous in the side chains of the protein, and are reasonably well resolved. Tertiary ^{13}C – ^{15}N or ^{13}C – ^{13}C contacts typically involve internuclear distances longer than 3.3 Å. The carbon pair distribution for nearest neighbors peaks at longer distances (4–5 Å) than for protons (near 3 Å). Thus tertiary heteronuclear contacts typically involve weak couplings in the range 30–150 Hz. Distance measurements in the order of 5 Å or longer in isolated pairs can be measured either homonuclear^{37–39} or heteronuclear.⁴⁰ The principal fundamental limitation for measurements in specifically labeled samples is related to the comparison of the coupling strength with dephasing rates for the transverse coherences involved in the coherent transfer processes or in the evolution of the detected spin (probably of the order of 10–100 Hz).

Measurements of tertiary ^{13}C – ^{15}N or ^{13}C – ^{13}C contacts encounter additional obstacles for application in uniformly labeled samples, however, if not applied with some thoughtful strategy. ^{13}C – ^{13}C and ^{13}C – ^{15}N long range contacts in uniformly labeled samples would be difficult to measure with broadbanded recoupling methods, because each ^{13}C is coupled to many directly neighboring ^{13}C nuclei. Firstly, spectra

involving mixing times long enough to achieve extensive population transfer to distant sites are expected to be very congested and poorly resolved, and cross peak intensities might not be related to distance in any simple way because of indirect coherence transfer pathways. More importantly, because the population transfers for solid state NMR typically occur through coherent evolution, the weaker couplings can become ‘truncated’ by the stronger couplings and ineffective for population transfer. Essentially every carbon in the protein has strongly bound neighbors. Measurements of weak couplings associated with bond lengths of 3–5 Å (ca. 50–250 Hz) in the presence of one bond couplings (ca. 2100 Hz) and several two bond couplings (ca. 500 Hz) is not straightforward. If a non-selective recoupling sequence is used with a uniformly labeled sample, then each carbon evolves coherently under the joint effect of several strong couplings and many weak couplings simultaneously. Such experiments would be expected to fail completely in the sense that very little magnetization is expected to reach long range tertiary contacts under a ‘total recoupling’ scheme.

The problem of detecting weak dipolar couplings can be met with two kinds of solutions. Introduction of ‘odd-alternate’ or ‘checkerboard’ labeling schemes, for example based on growth from 2- ^{13}C glycerol or 1–3- ^{13}C glycerol and use of specific bacterial strains,¹⁹ largely eliminates directly neighboring spins, making the detection of tertiary contacts possibly with simple non-selective recoupling protocols such as spin diffusion. These protocols can be used to provide dilute ^{13}C spins propitious for high resolution MAS spectroscopy and useful distance measurements.⁴¹ These schemes were used in the analysis of tertiary contacts in α -spectrin (Oshkinat et al., unpublished). Introduction of 2- ^{13}C -glycerol while supplementing the growth medium with unlabeled amino acids, results in ^{13}C labels on the His C^δ , C^α of Ser Gly and Cys C^α , Trp (C^α , $\text{C}^{\epsilon 2}$, $\text{C}^{\epsilon 3}$, $\text{C}^{\delta 2}$), Phe (C^α , C^γ , $\text{C}^{\epsilon 1}$), Tyr (C^α , C^γ , $\text{C}^{\epsilon 1}$), Ala C^α , Val C^α , and Leu (C' , C^β , C^γ). Because of the sparse nature of the labels in this particular scheme, relatively few long range constraints are expected. Roughly 0.3–0.5 tertiary constraints per residue are expected from these schemes.

Alternatively, a uniformly enriched sample can be characterized using tailored sequences based on selective recoupling of non-bonded functional groups. Spectrally selective sequences are analogous to non-selective recoupling sequences in that RF cycle times relate to the spatial (MAS) averaging in such a way that the net effect of the dipolar coupling is non-zero. They differ from non-selective sequences partly in that weak RF fields are used so that a dipolar matching condition may be met for one spectral band corresponding to carbons of one class of functional groups, but the dipolar recoupling condition is not met for most other functional groups. The recoupling conditions can therefore be established for tertiary but not primary contacts. For example, amide nitrogen and carbon methyl moieties are never in direct contact in proteins and only for alanine are they in a ‘two-bond’ arrangement. Therefore, tertiary contacts of this type will not usually be in competition with strong couplings in the same spectral band. These groups can be selectively recoupled using the selective CP experiment⁴² with the nitrogen carrier non-selectively covering all amides while the carbon selectively sweeps the methyl region. This approach was used to detect numerous tertiary contacts in ubiquitin (Rienstra et al., in preparation). Analogously, REDOR experiments that selectively probe long

range contacts have also been demonstrated in tripeptides.⁴³ On the other hand, band-selective homonuclear sequences also have a lot of promise for detecting relatively long range correlations, for example couplings between methyl and carbonyl ¹³C nuclei. These include rotational resonance tickling,⁴⁴ or DREAM.⁴⁵

How many tertiary contacts of this type are expected in a protein structure? A cursory count of heteroatom pairs (i.e., pairs involving ¹³C and ¹⁵N rather than ¹H), at moderate distances (up to 5 Å), involving distant amino acids in the primary sequence (separated by more than four residues) indicates that several contacts per residue are expected. Which can practically be measured? Spectral overlap of the weakly bound pair of nuclei with strongly coupled neighbors should be avoided. Experiments are likely to work well for tertiary contacts involving the following kinds of functional groups: methyl–N, methyl–CO, aromatic–N aromatic–CO, methyl–methyl, CO–CO and methyl aromatic. Back-bone methyl contacts are both numerous (ca. 0.3–1 tertiary contact per residue in a typical protein) and practical to measure with the pulse sequences listed above. Backbone aromatic contacts require full assignments of the congested aromatic spin systems, and require decoupling of the neighboring aromatic carbons so that the long range contact can be developed. These are formidable tasks, which will require development of new pulse sequences. Long-range contacts between pairs of backbone sites, i.e., CO–CO or C α – C α constraints, are numerous (0.5–1 per residue); these contacts will primarily report on backbone–backbone hydrogen bonds and provide constraints for the secondary structure. Side chain–side chain contacts include methyl–methyl and aromatic–methyl contacts. These are typically few in number (<0.3 per residue) but are located in the hydrophobic core and can provide crucial information on tertiary contacts. The combination of these tertiary constraints (backbone–backbone, backbone–side chain and side chain–side chain) might result in more than one long-range constraint per residue, which will be practically measurable with a handful of multi-dimensional experiments. As conceived above, each experiment would have to be set up and run separately, which would be rather time intensive.

Dipolar splittings in aligned liquids also provide constraints on torsion angles.⁴⁶ These splittings offer a relationship between the direction of a local functional group and a fixed global axis system, and are independent from the local torsional constraints or the tertiary contacts. It is clear that these measurements have significantly sharpened solution NMR structures, and have provided the main constraint for solid NMR structures of aligned static samples. The role that such constraints might play for solid state studies, i.e., utilization of aligned microcrystals or membranes, remains to be investigated, but also appears to be quite promising.⁴⁷

In summary, data from many experiments would be combined in order to have a large number of structural constraints: 1–2 tertiary contacts per residue in aggregate from separate selective recoupling experiments involving the pairs. N amide–Me, N amide–aromatic, CO–Me, CO–CO, Me–aromatic, and Me–Me. Proteins labeled in an odd-alternate pattern using specific metabolic pathways that might also provide constraints would be useful complements to the selective recoupling data. Additional data could be available from the use of ordered samples and torsion measurements.

3 STRUCTURE CALCULATIONS

How many contacts are needed to define the tertiary structure, and, procedurally, how can these structural constraints be used to compute structures? Protocols for analysis of tertiary constraints to define a three-dimensional structure are expected to be highly analogous to those used for solution NMR-derived nuclear Overhauser effects (NOEs).⁴⁸ Recently, we simulated carbon homonuclear structural constraints corresponding to both approaches, using known protein structures and simple assumptions about information that may be potentially accessible using selective labeling or selective recoupling schemes and knowledge of the ψ or ϕ torsional angles. Constraint lists for bovine pancreatic trypsin inhibitor (BPTI) were generated from the crystal structure (PDB entry 5pti.pdb)⁴⁹ (using the program 'ANALOGY', available from C. Geourjon, c.geourjon@ibcp.fr). Ensembles of 50 structures were calculated using X-PLOR; the 10 best structures were chosen on the criteria of minimum energy and violations, and the root mean squared deviation (RMSD) with respect to the crystal structure was calculated using the program MOLMOL.⁵⁰ A constraint set corresponding to all carbon–carbon contacts up to 5 Å can be used to determine high quality structures, i.e., with <1 Å RMSD; a variety of subsets of these contacts produced acceptable structures so long as more than one long range contact per residue was included. Combinations of the constraints discussed in the previous section offer a robust basis for structure; even if incomplete (<50%) data sets are assumed, high quality structures result (RMSD 1–2 Å). Correlations between backbone carbonyl and side chain carbons are of particular significance because they are numerous (>1 per residue), in many cases practically reasonable to measure, and appear to provide key information to constrain the tertiary structure. For example, 44 tertiary constraints from among the 86 that would result from selective recoupling of carbonyl methyl and aromatic carbons, result in a well-defined structure with an RMS of 1.9 Å. While a more honest assessment of the capability of solid state NMR derived structural parameters to constrain structures awaits actual data sets, these calculations are encouraging; they show that tertiary contacts derived from solid state NMR experiments may be sufficient to determine the correct fold.

Membrane proteins are among the most important targets for structural studies by solid state NMR due to their insolubility and the difficulties encountered in crystallization. The statistical distributions of distances typically encountered in membrane proteins such as bacteriorhodopsin and porin is somewhat different as contrasted with globular proteins. The percentage of amino acids with methyl bearing side-chains groups, and the related constraints, is typically much higher than for BPTI. Interhelical contacts in helical membrane proteins are mainly established through the methyl and aromatic groups of hydrophobic residues. The number of backbone–backbone tertiary contacts was negligible and not of practical importance for helical secondary structure, while for beta sheet structures these are of course more important. Many membrane proteins are ring-like oligomeric structures, which pose additional problems in interpretation. Clearly some fundamental issues for the study of these proteins will be the extent of resolution among the aliphatic side chains, which provide many of the long

range contacts, and the use of ambiguous restraints (i.e., restraints involving unidentified residues) in structure determination.

In conclusion, the past few years have seen rapid growth in the success of solid state NMR to study uniformly or extensively labeled proteins. Assignments of many proteins will clearly be within reach, and structural constraints are forthcoming as well. Protein constraint sets, analyzed with distance geometry simulated annealing protocols, appear to be capable of generating high resolution structures. Selective recoupling techniques among hydrophobic side chains and the carbonyl of the backbone appear to be especially promising, particularly if accompanied with measurements of torsional constraints. Alternative computational methods, such as methods for using ambiguous constraints⁵¹ and knowledge-based methods involving sparse data sets, might also be important for long term success.

1 INTRODUCTION

The last few years have seen a quantum jump in both the accuracy of the determination and in the size of protein structures that can be determined by NMR.¹ Thus it is now possible to determine the structures of proteins in the 15–25 kDa range at a resolution comparable to 0.2 nm resolution for crystal structures.² This advance is attributable to the development of three- and four-dimensional heteronuclear NMR techniques which circumvent problems associated with chemical shift overlap and degeneracy, on the one hand, and large linewidths on the other.^{1,3–5} In this article, we summarize some of these developments and illustrate their application to the structure determination of interleukin-1 β (IL-1 β),⁶ a complex of calmodulin with a target peptide,⁷ and a complex of the DNA binding domain of the transcription factor GATA-1 with its cognate DNA target site.⁸

2 GENERAL STRATEGY FOR THE DETERMINATION OF THREE-DIMENSIONAL STRUCTURES OF LARGER PROTEINS AND PROTEIN COMPLEXES BY NMR

The main source of geometric information used in protein structure determination lies in the nuclear Overhauser effect

(NOE) which can be used to identify protons separated by less than 0.5 nm.⁹ This distance limit arises from the fact that the NOE is proportional to the inverse sixth power of the distance between the protons. Hence the NOE intensity falls off very rapidly with increasing distance between proton pairs. Despite the short range nature of the observed interactions, the short approximate interproton distance restraints derived from the NOE measurements can be highly conformationally restrictive, particularly when they involve residues that are far apart in the sequence but close together in space.

The power of NMR over other spectroscopic techniques results from the fact that every proton gives rise to an individual resonance in the spectrum which can be resolved by higher (i.e. two, three and four) dimensional techniques. Bearing this in mind, the principles of structure determination by NMR can be summarized very simply by the scheme depicted in Figure 1. The first step is to obtain sequential resonance assignments using a combination of through-bond and through-space correlations; the second step is to obtain stereospecific assignments at chiral centers and torsion angle restraints using three-bond scalar couplings combined with intrasidue and sequential interresidue NOE data; the third step is to identify through-space connectivities between protons separated by less than 0.5 nm and, finally, the fourth step involves calculating three-dimensional structures on the basis of the amassed interproton distance and torsion angle restraints using one or more of a number of algorithms^{10–12} such as distance geometry and/or simulated annealing. It is not essential to assign all the NOEs initially. Indeed, many may be ambiguous and several possibilities may exist for their assignments. However, once a low-resolution structure has been calculated from a subset of the NOE data which can be interpreted unambiguously, it is then possible to employ iterative methods to resolve the vast majority of ambiguities. Consider, for example, an NOE cross peak which could be attributable to a through-space interaction between either protons A and B or between protons A and C. Once a low-resolution structure is available it is usually possible to discriminate between these two possibilities. Thus, if protons A and C are significantly greater than 0.5 nm apart while protons A and B are less than 0.5 nm apart, it is clear that the cross peak must arise from an NOE between protons A and B.

The quality of an NMR protein structure determination increases as the number of restraints increase.^{1,4,13–15} This progression in coordinate precision is illustrated in Figure 2 which shows four generations of structures, ranging from the first generation which simply provides a picture of the polypeptide fold with little detail, to the fourth generation which is broadly equivalent to a 0.2 nm resolution X-ray structure.

2.1 Sequential Resonance Assignment

Conventional sequential resonance assignment relies on two-dimensional homonuclear ^1H – ^1H correlation experiments to identify amino acid spin systems coupled with two-dimensional ^1H – ^1H NOE experiments to identify sequential connectivities along the backbone of the type $\text{C}^\alpha\text{H}(i)$ – $\text{NH}(i + 1, 2, 3, 4)$, $\text{NH}(i)$ – $\text{NH}(i \pm 2)$ and $\text{C}^\alpha\text{H}(i)$ – $\text{C}^\beta\text{H}(i + 3)$.^{16,17} This methodology has been successfully applied to proteins of less than 100 residues. For larger proteins, the

Figure 1 Summary of the general strategy employed to solve three-dimensional structures of macromolecules by NMR. (Adapted from G. M. Clore and A. M. Gronenborn, *Science*, 1991, **252**, 1390)

spectral complexity is such that two-dimensional experiments no longer suffice, and it is essential to increase the spectral resolution by increasing the dimensionality of the spectra.¹⁸ In some cases it is still possible to apply the same strategy by making use of three-dimensional heteronuclear (^{15}N or ^{13}C) edited experiments to increase the spectral resolution, as illustrated in Figure 3.^{19–22} In many cases, however, numerous ambiguities still remain and it is advisable to adopt a sequential assignment strategy based solely on well defined heteronuclear scalar couplings.^{3,5,23–25} The double and triple resonance experiments that we currently use, and the correlations that they demonstrate, are summarized in Table 1. With the advent of pulse field gradients to eliminate undesired coherence transfer pathways,²⁶ it is now possible to employ only two-step phase cycles without any loss in sensitivity (other than that due to the reduction in measurement time) such that each three-dimensional experiment can be recorded in as little as 7 h. In most cases, however, signal-to-noise ratio requirements necessitate 1–3 days of measuring time, depending on the experiment.

2.2 Stereospecific Assignments and Torsion Angle Restraints

It is often possible to obtain stereospecific assignments of β -methylene protons on the basis of a qualitative interpretation of the homonuclear $^3J(\alpha, \beta)$ coupling constants and the intraresidue NOE data involving the NH, C^αH and C^βH protons.^{27,28} A more rigorous approach, which also permits one to obtain ϕ , ψ , and χ_1 restraints, involves the application of a conformational grid search of ϕ, ψ, χ_1 space on the basis of the homonuclear $^3J(\text{N}-\alpha, \text{H})$ and $^3J(\alpha, \beta)$ coupling constants (which are related to ϕ and χ_1 , respectively), and the intraresidue and sequential ($i \pm 1$) interresidue NOEs involving the NH, C^αH and C^βH protons.^{29,30} This

information can be supplemented by the measurement of heteronuclear $^3J(\text{N}, \text{H}-\beta)$ and $^3J(\text{CO}, \text{H}-\beta)$ couplings which are also related to χ_1 .³¹ Stereospecific assignment of valine methyl groups can be made on the basis of $^3J(\text{C}-\gamma, \text{CO})$ and $^3J(\text{N}, \text{C}-\gamma)$ couplings,³¹ as well as on the basis of the pattern of intraresidue NOEs involving the NH, C^αH and C^γH protons.³² Finally, stereospecific assignments of leucine methyl groups can be made on the basis of heteronuclear $^3J(\text{C}-\delta, \text{C}-\alpha)$ and $^3J(\text{C}-\delta, \text{H}-\beta)$ couplings³¹ in combination with the pattern of intraresidue NOEs, provided that the stereospecific assignment of the β -methylene protons and the χ_1 rotamer have been previously determined.³³

2.3 Assignment of Through-space Proton-Proton Interactions within a Protein

While the panoply of three-dimensional heteronuclear experiments is sufficient for the purposes of spectral assignment, yet further increases in resolution are required for the reliable identification of NOE through space interactions. This can be achieved by extending the dimensionality still further to four dimensions.³⁴ This is illustrated in Figure 4. Consider a simple two-dimensional spectrum demonstrating 11 cross peaks from aliphatic resonances to a single NH resonance position. In the two-dimensional spectrum it is impossible to ascertain whether this involves one NH proton or many. Extending the spectrum to three dimensions by separating the NOE interactions according to the ^{15}N chemical shift of the nitrogen attached to each amide proton reveals that there are three NH protons involved. The identity of the originating aliphatic protons, however, is only specified by their proton chemical shifts. Yet the extent of spectral overlap in the aliphatic region of the spectrum vastly exceeds that in the amide region. This can be resolved by adding a further dimension in which each plane of the three-dimensional spectrum now constitutes a cube in the

1st Generation
 ~ 7 restraints per residue
 rmsd: 0.15 nm for backbone atoms
 0.20 nm for all atoms
 Example: purothionin

2nd Generation
 ~ 10 restraints per residue
 rmsd: 0.09 nm for backbone atoms
 0.12 nm for all atoms
 Example: BDS-I

3rd Generation
 ~ 13 restraints per residue
 rmsd: 0.07 nm for backbone atoms
 0.09 nm for all atoms
 Example: BDS-I

4th Generation
 ~ 16 restraints per residue
 rmsd: 0.04 nm for backbone atoms
 0.09 nm for all atoms
 ≤ 0.05 nm for ordered side chains
 Example: Interleukin-8

Figure 2 Illustration of the progressive improvement in the precision and accuracy of NMR structure determinations with increasing number of experimental restraints. All the structures have been calculated using the hybrid distance geometry, simulated annealing method, and in each case the NOE derived interproton distance restraints have been grouped into the three broad ranges: 0.18–0.27, 0.18–0.33, and 0.18–0.5 nm, corresponding to strong, medium and weak NOEs, respectively. (Adapted from G. M. Clore and A. M. Gronenborn, *Science*, 1991, **252**, 1390)

four-dimensional spectrum edited by the ^{13}C shift of the carbon atom attached to each aliphatic proton. In this manner, each ^1H – ^1H NOE interaction is specified by four chemical shift coordinates, the two protons giving rise to the NOE and the heavy atoms to which they are attached. The resolving power of four-dimensional heteronuclear-edited NOE spectroscopy is illustrated in Figure 5.

Because the number of NOE interactions present in each two-dimensional plane of a four-dimensional $^{13}\text{C}/^{15}\text{N}$ or $^{13}\text{C}/^{13}\text{C}$ edited NOESY spectrum is so small, the inherent resolution in a four-dimensional spectrum is extremely high, despite the low level of digitization. Indeed, spectra with equivalent resolution can be recorded at magnetic field strengths considerably lower than 600 MHz, although this

Figure 3 Comparison of the NH- $C^{\alpha}H/C^{\beta}H$ region of a two-dimensional ^{15}N -edited NOESY spectrum (a) with that of a single plane taken from the three-dimensional ^{15}N -edited NOESY spectrum of interleukin-1 β (b), illustrating the increase in spectral resolution afforded by increasing the dimensionality from two to three. (Adapted from D. Marion, P. C. Driscoll, L. E. Kay, P. T. Wingfield, A. Bax, A. M. Gronenborn, and G. M. Clore, *Biochemistry*, 1989, **28**, 6150)

Table 1 Summary of Correlations Observed in the Three-dimensional Double and Triple Resonance Experiments used for Sequential and Side-Chain Assignments in our Laboratory

Experiment	Correlation	J Coupling ^a
^{15}N edited HOHAHA	$C^{\alpha}H(i) - ^{15}N(i) - NH(i)$	$^3J(N-\alpha, H)$
	$C^{\beta}H(i) - ^{15}N(i) - NH(i)$	$^3J(N-\alpha, H)$ and $^3J(\alpha, \beta)$
HNHA	$C^{\alpha}H(i) - ^{15}N(i) - NH(i)$	$^3J(N, H)$
H(CA)NH	$C^{\alpha}H(i) - ^{15}N(i) - NH(i)$	$^1J(N, C-\alpha)$
	$C^{\alpha}H(i-1) - ^{15}N(i) - NH(i)$	$^2J(N, C-\alpha)$
HNCA	$^{13}C^{\alpha}(i) - ^{15}N(i) - NH(i)$	$^1J(N, C-\alpha)$
	$^{13}C^{\alpha}(i-1) - ^{15}N(i) - NH(i)$	$^2J(N, C-\alpha)$
HN(CO)CA	$^{13}C^{\alpha}(i-1) - ^{15}N(i) - NH(i)$	$^1J(N, CO)$ and $^1J(C-\alpha, CO)$
HNCO	$^{13}CO(i-1) - ^{15}N(i) - NH(i)$	$^1J(N, CO)$
HCACO	$C^{\alpha}H(i) - ^{13}C^{\alpha}(i) - ^{13}CO(i)$	$^1J(C-\alpha, CO)$
HCA(CO)N	$C^{\alpha}H(i) - ^{13}C^{\alpha}(i) - ^{15}N(i+1)$	$^1J(C-\alpha, CO)$ and $^1J(N, CO)$
CBCA(CO)NH	$^{13}C^{\beta}(i-1)/^{13}C^{\alpha}(i-1) - ^{15}N(i) - NH(i)$	$^1J(C-\alpha, CO)$, $^1J(N, CO)$ and $^1J(C, C)$
CBCANH	$^{13}C^{\beta}(i)/^{13}C^{\alpha}(i) - ^{15}N(i) - NH(i)$	$^1J(N, C-\alpha)$ and $^1J(C, C)$
	$^{13}C^{\beta}(i-1)/^{13}C^{\alpha}(i-1) - ^{15}N(i) - NH(i)$	$^2J(N, C-\alpha)$ and $^1J(C, C)$
HBHA(CO)NH	$C^{\beta}H(i-1)/C^{\alpha}H(i-1) - ^{15}N(i) - NH(i)$	$^1J(C-\alpha, CO)$, $^1J(N, CO)$ and $^1J(C, C)$
HBHANH	$C^{\beta}H(i)/C^{\alpha}H(i) - ^{15}N(i) - NH(i)$	$^1J(N, C-\alpha)$ and $^1J(C, C)$
	$C^{\beta}H(i-1)/C^{\alpha}H(i-1) - ^{15}N(i) - NH(i)$	$^2J(N, C-\alpha)$ and $^1J(C, C)$
C(CO)NH	$^{13}C^j(i-1) - ^{15}N(i) - NH(i)$	$^1J(C-\alpha, CO)$, $^1J(N, CO)$ and $^1J(C, C)$
H(CCO)NH	$H^j(i-1) - ^{15}N(i) - NH(i)$	$^1J(C-\alpha, CO)$, $^1J(N, CO)$ and $^1J(C, C)$
HCCH-COSY	$H^j - ^{13}C^j - ^{13}C^{j+1} - H^{j+1}$	$^1J(C, C)$
HCCH-TOCSY	$H^j - ^{13}C^j \dots ^{13}C^{j+n} - H^{j+n}$	$^1J(C, C)$

^aIn addition to the couplings indicated, all the experiments make use of the $^1J(C, H)$ (≈ 140 Hz) and/or $^1J(N, H)$ (≈ 95 Hz) couplings. The values of the couplings employed are as follows: $^3J(N-\alpha, H) \approx 3-10$ Hz, $^1J(C, C) \approx 35$ Hz, $^1J(C-\alpha, CO) \approx 55$ Hz, $^1J(N, CO) \approx 15$ Hz, $^1J(N, C-\alpha) \approx 11$ Hz, $^2J(N, C-\alpha) \approx 7$ Hz.

Figure 4 Schematic illustration of the progression and relationship between two-, three-, and four-dimensional heteronuclear-edited NMR spectroscopy. (Adapted from G. M. Clore and A. M. Gronenborn, *Science*, 1991, **252**, 1390)

would obviously lead to a reduction in sensitivity. Furthermore, it can be calculated that four-dimensional spectra with virtual lack of resonance overlap and good sensitivity can be obtained on proteins with as many as 400 residues. Thus, once complete ^1H , ^{15}N , and ^{13}C assignments are obtained, analysis of four-dimensional $^{15}\text{N}/^{13}\text{C}$ and $^{13}\text{C}/^{13}\text{C}$ edited NOE spectra^{34–37} should permit the automated assignment of almost all NOE interactions.

3 APPLICATION OF THREE- AND FOUR-DIMENSIONAL NMR TO STRUCTURE DETERMINATION OF LARGER PROTEINS: THE STRUCTURE OF INTERLEUKIN-1 β

While the potential of heteronuclear three- and four-dimensional NMR methods in resolving problems associated with both extensive resonance overlap and large linewidths

is obvious, how does this new approach fare in practice? In this regard it should be borne in mind that resonance assignments are only a means to an end, and the true test of multidimensional NMR lies in examining its success in solving the problem which it was originally designed to tackle, namely the determination of high-resolution three-dimensional structures of larger proteins in solution.

The first successful demonstration of these new methods was the determination of the high-resolution solution structure of interleukin-1 β (IL-1 β), a cytokine of 153 residues and molecular weight 17.4 kDa, which plays a key role in the immune and inflammatory responses.⁶ At the time IL-1 β was 50% larger, in terms of the number of residues, than the previously largest protein structures solved by NMR, namely human³⁸ and *Escherichia coli*³⁹ thioredoxin which have 105 and 108 residues, respectively. Moreover, IL-1 β still represents one of the most highly refined and precise structures for proteins of this size solved by NMR.

Despite extensive analysis of two-dimensional spectra obtained at different pH values and temperatures, as well as

Figure 5 Example of the increase in spectral resolution afforded by four-dimensional ${}^{13}\text{C}/{}^{13}\text{C}$ -edited NOE spectroscopy, illustrated with IL-1 β . (a) ${}^1\text{H}(F_2)$ - ${}^1\text{H}(F_4)$ plane of the four-dimensional spectrum at $\delta^{13}\text{C}(F_1) = 44.3$ ppm and $\delta^{13}\text{C}(F_3) = 34.6$ ppm; the region between 1 and 2 ppm is boxed in and the arrow indicates the position of the Lys77 $\text{C}'\text{H}$ - C^βH NOE cross peak. (b) Two-dimensional ${}^1\text{H}$ - ${}^1\text{H}$ NOE spectrum between 1 and 2 ppm; the X marks the chemical shift position of the Lys77 $\text{C}'\text{H}$ - C^βH NOE cross peak seen in (a). (c, d) Positive and negative contours in the ${}^{13}\text{C}(F_1)$ - ${}^{13}\text{C}(F_3)$ plane of the four-dimensional spectrum at the ${}^1\text{H}$ chemical shift coordinates $\delta^1\text{H}(F_2) = 1.39$ ppm and $\delta^1\text{H}(F_4) = 1.67$ ppm corresponding to the Lys77 $\text{C}'\text{H}$ - C^βH NOE cross peak seen in (a) and the X mark shown in (b). Because extensive folding is employed, the ${}^{13}\text{C}$ chemical shifts are given by $x \pm n\text{SW}$, where x is the ppm value listed in the figure, n is an integer, and SW is the spectral width (20.71 ppm). Peaks folded an even number of times are of opposite sign to those folded an odd number of times. All the peaks in (a) are positive, except for the two indicated by an asterisk which are negative. (Adapted from G. M. Clore and A. M. Gronenborn, *Science*, 1991, **252**, 1390)

examination of two-dimensional spectra of mutant proteins, it did not prove feasible to obtain unambiguous ${}^1\text{H}$ assignment for more than about 30% of the residues of interleukin-1 β .²² Thus, any further progress could only be made by resorting to higher dimensionality heteronuclear NMR. The initial step involved the complete assignment of the ${}^1\text{H}$, ${}^{15}\text{N}$, and ${}^{13}\text{C}$ resonances of the backbone and side chains using

many of the double and triple resonance three-dimensional experiments listed in Table 1.^{22,40,41} In the second step, backbone and side-chain torsion angle restraints, as well as stereospecific assignments for β -methylene protons, were obtained by means of a three-dimensional systematic grid search of ϕ, ψ, χ_1 space.³⁰ In the third step, approximate interproton distance restraints between nonadjacent residues

were derived from analysis of three- and four-dimensional heteronuclear-edited NOE spectra. Analysis of the three-dimensional heteronuclear-edited NOE spectra alone was sufficient to derive a low-resolution structure on the basis of a small number of NOEs involving solely NH, C α H and C β H protons.⁴² However, further progress using three-dimensional NMR was severely hindered by the numerous ambiguities still present in these spectra, in particular for NOEs arising from the large number of aliphatic protons. Thus, the four-dimensional heteronuclear-edited NOE spectra proved to be absolutely essential for the successful completion of this task. In addition, the proximity of backbone NH protons to bound structural water molecules was ascertained from a three-dimensional ¹⁵N-separated ROESY spectrum which permits one to distinguish specific protein–water NOE interactions from chemical exchange with bulk solvent.⁴³ In this regard it should be emphasized that all the NOE data were interpreted in as conservative a manner as possible, and were simply classified into three distance ranges: 0.18–0.27, 0.18–0.33, and 0.18–0.50 nm, corresponding to strong, medium, and weak intensity NOEs, respectively.

With an initial set of experimental restraints in hand, three-dimensional structure calculations were initiated using the hybrid distance geometry–dynamical simulated annealing method.⁴⁴ A key aspect of the overall strategy lies in the use of an iterative approach whereby the experimental data are reexamined in the light of the initial set of calculated structures in order to resolve ambiguities in NOE assignments, to obtain more stereospecific assignments (e.g. the α -methylene protons of glycine and the methyl groups of valine and leucine) and torsion angle restraints, and to assign backbone hydrogen bonds associated with slowly exchanging NH protons as well as with bound water molecules. The iterative cycle comes to an end when all the experimental data have been interpreted.

The final experimental data set for IL-1 β comprised a total of 3146 approximate and loose experimental restraints made up of 2780 distance and 366 torsion angle restraints.⁶ This represents an average of about 21 experimental restraints per residue. If one takes into account that interresidue NOEs affect two residues, while intraresidue NOE and torsion angle restraints only affect individual residues, the average number of restraints influencing the conformation of each residue is approximately 33. Superpositions of the backbone atoms and selected side chains for 32 independently calculated structures are shown in Figures 6(b) and 6(d). All 32 structures satisfy the experimental restraints within their specified errors, display very small deviations from idealized covalent geometry, and have good nonbonded contacts. It can be seen that both the backbone and ordered side chains are exceptionally well defined. Indeed, the atomic root-mean-square (rms) distribution about the mean coordinate positions is 0.04 nm for the backbone atoms, 0.08 nm for all atoms, and 0.05 nm for side chains with $\leq 40\%$ of their surface (relative to that in a tripeptide Gly-X-Gly) accessible to solvent.⁶

The structure of IL-1 β itself resembles a tetrahedron and displays three-fold internal pseudosymmetry. There are 12 β -strands arranged in an exclusively antiparallel β -structure, and six of the strands form a β -barrel [seen in the front of Figure 6(a)] which is closed off at the back of the molecule by the other six strands. Each repeating topological unit is composed of 5 strands arranged in an antiparallel manner with respect to each other, and one of these units is shown in Figure 6(c).

Water molecules occupy very similar positions in all three topological units, as well as at the interface of the three units, and are involved in bridging backbone hydrogen bonds. Thus, in the case of the topological unit shown in Figure 6(c), the water molecule labeled W5 accepts a hydrogen bond from the NH of Phe112 in strand IX and donates two hydrogen bonds to the backbone carbonyls of Ile122 in strand X and Thr144 in strand XII. The packing of some internal residues with respect to one another, as well as the excellent definition of internal side chains, is illustrated in Figure 6(d). Because of the high resolution of the IL-1 β structure it was possible to analyze in detail side-chain–side-chain interactions involved in stabilizing the structure. In addition, examination of the structure in the light of mutational data permitted us to propose the presence of three distinct sites involved in the binding of IL-1 β to its cell surface receptor.⁶

4 COMBINING EXPERIMENTAL INFORMATION FROM CRYSTAL AND SOLUTION STUDIES: JOINT X-RAY AND NMR REFINEMENT

It is clear from the preceding discussion that NMR is a valid method, alongside X-ray crystallography, for determining high-resolution structures of small to medium sized proteins of less than about 35 kDa. IL-1 β offers an ideal system for comparing the results of NMR and X-ray crystallography as, in addition to the solution structure, there are three independently solved X-ray structures at 0.2 nm resolution of the same crystal form.^{45–47} The backbone atomic rms difference between the NMR and the X-ray structures is about 0.1 nm, with the largest differences being confined to some of the loops and turns connecting the β -strands.² Interestingly, however, the atomic rms distribution of the 32 calculated solution structures about their mean coordinate positions (about 0.04 nm for the backbone atoms, about 0.08 nm for all atoms, and about 0.05 nm for all atoms of internal residues) is approximately the same as the atomic rms differences between the three X-ray structures, indicating that the positional errors in the atomic coordinates determined by the two methods are similar.² Upon initial inspection, the X-ray structures appear to be incompatible with the NMR data, as manifested by a relatively large number of NOE and torsion angle violations and, conversely, the NMR structure fits the X-ray data poorly with an *R* factor of 40–50%. Because of the very different nature of the two methods, it is not immediately apparent that these discrepancies reflect genuine differences between the solution and X-ray structures or whether they reflect differences in the computational procedures employed. To analyze this in more detail we have developed a new method of structure determination in which the NMR and X-ray data are combined and used simultaneously in the structure refinement.⁴⁸ Using this approach we have shown that a model can readily be generated from a joint NMR/X-ray refinement which is compatible with the data from both techniques. Thus, there are only minimal violations of the NMR restraints (NOEs and torsion angles), the value of the crystallographic *R* factor is comparable to, if not better than, that derived from refinement against the crystallographic data alone, and the deviations from idealized covalent geometry are small. In addition, the *R* free⁴⁹ for the model refined with the NMR and

Figure 6 Solution structure of IL-1 β determined by three- and four-dimensional heteronuclear NMR spectroscopy. (a) Ribbon diagram of the polypeptide fold. (b) Superposition of the backbone (N, C α , and C) atoms of 32 simulated annealing structures calculated from the experimental NMR data. (c) Superposition of the backbone (N, C α , C, and O) atoms of one of the three repeating topological units, illustrating the position of tightly bound water at the interface of the three central strands of the unit. (d) Superposition of all atoms (excluding protons) for selected side chains. The diagram in (a) was made using the program MOLSCRIPT.¹⁰² The coordinates are from Clore et al.⁶ (PDB accession code 611B). (Adapted from G. M. Clore, P. T. Wingfield, and A. M. Gronenborn, *Biochemistry*, 1991, **30**, 2315)

X-ray restraints is smaller than that of the model obtained by conventional crystallographic refinement, indicating that the crystallographic phases obtained by the joint NMR/X-ray refinement are more accurate. Moreover, the few NMR observations that are still violated by the model serve as an indicator for genuine differences between the crystal and solution structures.

The implications of the joint NMR/X-ray refinement method to structural biology are of considerable significance. In particular, the full potential and future use of the method will be for structure determinations of multidomain proteins, for which only low-resolution X-ray data for the entire protein are available but for which detailed structural information may be obtained by NMR on the individual domains. Using the joint X-ray/NMR refinement approach in such cases will open the way to the study of proteins which may otherwise never be structurally accessible by either of the two methods alone.

5 STRUCTURE DETERMINATION OF PROTEIN–PEPTIDE AND PROTEIN–DNA COMPLEXES

Provided the ligand (e.g. a peptide, an oligonucleotide, or a drug) presents a relatively simple spectrum that can be assigned by two-dimensional methods, the most convenient strategy for dealing with protein–ligand complexes involves one in which the protein is labeled with ^{15}N and ^{13}C and the ligand is unlabeled (i.e. at natural isotopic abundance).⁵⁰ It is then possible to use a combination of heteronuclear filtering and editing to design experiments in which correlations involving only protein resonances, only ligand resonances, or only through-space interactions between ligand and protein are observed. These experiments are summarized in Table 2 and were first applied successfully to a complex of calmodulin with a target peptide from skeletal muscle myosin light chain kinase,⁷ and subsequently to the specific complex of the DNA binding domain of the transcription factor GATA-1 with its cognate DNA target site.⁸

5.1 The Structure of the Calmodulin–Target Peptide Complex

Calmodulin (CaM) is a ubiquitous Ca^{2+} binding protein of 148 residues which is involved in a wide range of cellular Ca^{2+} -dependent signaling pathways, thereby regulating the activity of a large number of proteins.⁵¹ The crystal structure of Ca^{2+} -CaM was solved a number of years ago.⁵² It is a dumb-bell shaped molecule with an overall length of about 6.5 nm and consisting of two globular domains, each of which contains two Ca^{2+} binding sites of the helix–loop–helix type, connected by a long, solvent exposed, rigid central helix some eight turns in length (residues 66–92). In solution, on the other hand, ^1H – ^{15}N NMR relaxation measurements have demonstrated unambiguously that the central helix is disrupted near its midpoint, with residues 78–81 adopting an essentially unstructured ‘random coil’ conformation which is so flexible that the N- and C-terminal domains of Ca^{2+} -CaM effectively tumble independently of each other.⁵⁸ Thus, in solution, the so-called ‘central helix’ is not a helix at all but is a ‘flexible tether’ the purpose of which is to keep the two domains in close proximity for binding to their target.

In order to understand the way in which Ca^{2+} -CaM recognizes its target sites, we set out to solve, in collaboration with Ad Bax, the solution structure of a complex of Ca^{2+} -CaM with a 26 residue peptide (known as M13) comprising residues 577–602 of the calmodulin binding domain of skeletal muscle myosin light chain kinase. The solution structure was determined on the basis of 1995 experimental NMR restraints including 133 interproton distance restraints between the peptide and the protein. The N-terminus (residues 1–5) and C-terminus (residues 147–148) of CaM, the tether connecting the two domains of CaM (residues 74–82), and the N-terminus (residues 1–2) and C-terminus (residues 22–26) of M13 were ill-defined by the NMR data and appear to be disordered in solution. The atomic rms distribution about the mean coordinate positions for the rest of the structure (i.e. residues 6–73 and 83–146 of CaM, and residues 3–21 of M13) is 0.1 nm for the backbone atoms and 0.14 nm for all atoms. Thus this structure represents a second generation

Table 2 Summary of Heteronuclear-filtered and -edited NOE Experiments used to Study Protein–Ligand Complexes Comprising a Uniformly $^{15}\text{N}/^{13}\text{C}$ Labeled Protein and an Unlabeled Ligand

Type of contact	Connectivity
<i>A Intramolecular protein contacts</i>

^aSimilar heteronuclear filtered two-dimensional correlation and Hartmann–Hahn spectra can also be recorded to assign the spin systems of the ligand.

structure in the classification of Clore and Gronenborn.¹ A stereoview showing a best fit superposition of the 24 calculated structures is shown in Figure 7(a).

The major conformational change in Ca^{2+} -CaM that occurs upon binding M13 involves an extension of the flexible tether (residues 78–81) in the middle of the ‘central’ helix of the solution structure of free Ca^{2+} -CaM to a long flexible loop extending from residues 74–81, flanked by two helices (residues 65–73 and 83–93), thereby enabling the two domains to come together, gripping the peptide rather like two hands capturing a rope. The hydrophobic channel formed by the two domains is complementary in shape to that of the peptide helix. This is clearly illustrated by the schematic ribbon drawings shown in Figures 7(b) and 7(c) which also serve to highlight the approximate two-fold pseudosymmetry of the complex. Thus, whereas the two domains of CaM are arranged in an approximately orthogonal manner to each other in the crystal structure of Ca^{2+} -CaM,⁵² in the Ca^{2+} -CaM-M13 complex they are almost symmetrically related by a 180° rotation about a two-fold axis. A large conformational change also occurs in the M13 peptide upon complexation from a random coil state to a well defined helical conformation. Indeed, the helix involves all the residues (3–21) of M13 that interact with CaM, while the N-terminus (residues 1–2) and C-terminus (residues 22–26) of the peptide which do not interact with CaM, remain disordered.

Upon complexation there is a decrease in the accessible surface area of CaM and M13 of 18.48 and 14.77 nm², respectively, which corresponds to a decrease in the calculated solvation free energy of folding⁵³ of 18 and 20 kcal mol⁻¹ (75–83 kJ mol⁻¹), respectively. This large decrease in solvation free energy would account for the very tight binding ($K_{\text{ass}} \approx 10^9 \text{ M}^{-1}$) of M13 to calmodulin. In addition, the accessible surface area of the portion of M13 (residues 3–21) in direct contact with CaM in the complex is only 4.94 nm² compared with an accessible surface of area 31.23 nm² for a random coil and 22.50 nm² for a helix. Thus, over 80% of the surface of the peptide in contact with CaM is buried.

In the view shown in Figure 7(b), the roof of the channel is formed by helices II (residues 29–38) and VI (residues 102–111) of the N- and C-terminal domains, respectively, which run antiparallel to each other; and the floor is formed by the flexible loop (residues 74–82) connecting the two domains and by helix VIII (residues 138–146) of the C-terminal domain. The front of the channel in Figure 7(b) and the left wall of the channel in Figure 7(c) are formed by helices I (residues 7–19) and IV (residues 65–73) and the mini-antiparallel β -sheet comprising residues 26–28 and 62–64, all from the N-terminal domain; the back of the channel in Figure 7(b) and the right wall of the channel in Figure 7(c) are formed by helices V (residues 83–93) and VIII (residues 138–146) and the miniantiparallel β -sheet comprising residues 99–101 and 135–137, all from the C-terminal domain. The two domains of CaM are staggered with a small degree of overlap such that the hydrophobic face of the N-terminal domain mainly contacts the C-terminal half of the M13 peptide, while the C-terminal domain principally interacts with the N-terminal half of M13 (Figure 7(b)).

The overall Ca^{2+} -CaM-M13 complex has a compact globular shape approximating to an ellipsoid with dimensions $4.7 \times 3.2 \times 3.0 \text{ nm}$. The helical M13 peptide passes through the center of the ellipsoid at an angle of about 45° to its

long axis. By way of contrast, the approximate dimensions of the Ca^{2+} -CaM X-ray structure are $6.5 \times 3.0 \times 3.0 \text{ nm}$.⁵² In addition, the calculated radius of gyration for Ca^{2+} -CaM-M13 is about 1.7 nm which is completely consistent with the decrease in the radius of gyration from about 2.1 to about 1.6 nm observed by both small angle X-ray and neutron scattering upon complexation of Ca^{2+} -CaM with M13.⁵⁴

The Ca^{2+} -CaM-M13 complex is stabilized by numerous hydrophobic interactions which are summarized in Figure 8. Particularly striking are the interactions of Trp4 and Phe17 of the peptide which serve to anchor the N- and C-terminal halves of M13 to the C-terminal and N-terminal hydrophobic patches of CaM, respectively [Figure 7(c)]. These interactions also involve a large number of methionine residues which are unusually abundant in CaM, in particular four methionine residues in the C-terminal domain (Met109, Met124, Met144, and Met145) and three methionine residues in the N-terminal domain (Met36, Met51, and Met71). As methionine is an unbranched hydrophobic residue extending over four heavy atoms (C- β , C- γ , S- δ , and C- ϵ), the abundance of methionine residues can generate a hydrophobic surface the detailed topology of which is readily adjusted by minor changes in side-chain conformation, thereby providing a mechanism to accommodate and recognize different bound peptides.⁵⁵

In addition to hydrophobic interactions, there are a number of possible electrostatic interactions that can be deduced from the calculated NMR structures. Putative interactions exist between the Arg and Lys residues of M13 and the Glu residues of CaM, and these are also included in Figure 8. Glu11 and Glu14 in helix I are within 0.5 nm of Lys5 and Lys6 of M13; Glu83, Glu84, and Glu87 in helix V of CaM are close to Lys19, Arg16, and Lys18, respectively, of M13; and Glu127 in helix VII of CaM is close to Arg3 of M13.

The solution structure of the Ca^{2+} -CaM-M13 complex explains a number of interesting observations. Studies of backbone amide exchange behavior have shown that upon complexation with M13, the amide exchange rates of residues 75–79 are substantially increased.⁵⁶ Prior NMR studies on Ca^{2+} -CaM indicated that the long central helix is already disrupted near its middle (from Asp78 to Ser81) in solution⁵⁷ and that large variations in the orientation of one domain relative to the other occur randomly with time.⁵⁸ The further disruption of the central helix upon complexation seen in the structure of the complex is manifested by the increased amide exchange rates, and supports the view of the central helix serving as a flexible linker between the two domains. Similarly, the structure of the complex explains the finding that as many as four residues can be deleted from the middle of the central helix without dramatically altering the stability or shape of the Ca^{2+} -CaM-M13 complex,^{59,60} as the long flexible loop connecting the two domains can readily be shortened without causing any alteration in the structure (see Figure 7). The observation from photoaffinity labeling studies that the two domains of CaM interact simultaneously with opposite ends of the peptide such that residue 4 of the peptide (numbering for M13) can be cross-linked to Met124 or Met144 of the C-terminal domain and that residue 13 of the peptide can be cross linked to Met71 of the N-terminal domain,⁶¹ is readily explained by the structural finding that the N-terminal half of the peptide interacts predominantly with the C-terminal domain, while the C-terminal half of the peptide interacts predominantly with the N-terminal domain (Figures 7 and 8).

Figure 7 Solution structure of the Ca²⁺-CaM-M13 peptide complex determined by three- and four-dimensional heteronuclear NMR spectroscopy. (a) Superposition of the backbone (N, C^α, and C) atoms of 24 simulated annealing structures calculated from the experimental NMR data; the N- and C-terminal domains of calmodulin are shown in blue and red, respectively, and the M13 peptide is in green; the restrained regularized average structure is highlighted. (b, c) Two orthogonal views of a schematic ribbon drawing representation of the structure with the N- and C-terminal domains of CaM in blue and purple, respectively, the M13 peptide in yellow, the hydrophobic side chains of the protein in red, and Trp4, Phe8, Val11, and Phe17 side chains of the peptide in green. The diagrams in (b) and (c) were generated using the program VISP.¹⁰³ The coordinates are from Ikura et al.⁷ (PDB accession code 1BBM). (Adapted from M. Ikura, G. M. Clore, A. M. Gronenborn, G. Zhu, C. B. Klee, and A. Bax, *Science*, 1992, **256**, 632)

Figure 8 Summary of residue pairs for which intermolecular NOEs between CaM and M13 are observed. CaM residues involved in hydrophobic interactions are boxed. Also included are potential electrostatic interactions between negatively charged Glu residues of CaM (shown in parentheses) and positively charged Lys and Arg residues of M13. (Adapted from M. Ikura, G. M. Clore, A. M. Gronenborn, G. Zhu, C. B. Klee, and A. Bax, *Science*, 1992, **256**, 632)

The observation that at least 17 residues of the M13 peptide from either skeletal muscle or smooth muscle are necessary for high affinity binding^{62,63} is readily explained by the intimate interactions of the C-terminal hydrophobic residue (i.e. Phe17) with the N-terminal domain of CaM by which the peptide is anchored. Finally, the structure accounts for experiments in which cross-linking of residues 3 and 146 of CaM, mutated to Cys, has no effect on the activation of myosin light chain kinase, even if the central helix is cleaved proteolytically at Lys77 by trypsin.⁶⁴ Thus, while the atoms of the residues 3 and 146 are 3.7 nm apart in the X-ray structure of Ca^{2+} -CaM, they are only about 2.0 nm apart in the solution structure of

the Ca^{2+} -CaM-M13 complex, which is close enough to permit cross-linking to occur.

A large body of experimental data shows that CaM binds to numerous proteins whose binding domains exhibit a propensity for α -helix formation.⁵¹ A comparison of these sequences reveals little homology. Nevertheless, many of the very tightly binding peptides ($K_{\text{ass}} \geq 5 \times 10^7 \text{ M}^{-1}$) have the common property of containing either aromatic residues or long-chain hydrophobic residues (Leu, Ile, or Val) separated by 12 residues, as summarized in Figure 9. In the case of M13, these two residues are Trp4 and Phe17 which are exclusively in contact with the C- and N-terminal domains, respectively,

Figure 9 Alignment of tightly binding ($K_{\text{ass}} \geq 5 \times 10^7 \text{ M}^{-1}$) CaM binding sequences based on the structural role of Trp4 and Phe17 in anchoring the M13 peptide to the C- and N-terminal domains, respectively, of CaM. (Adapted from M. Ikura, G. M. Clore, A. M. Gronenborn, G. Zhu, C. B. Klee, and A. Bax, *Science*, 1992, **256**, 632)

of CaM, (Figure 7 and Figure 8). Given that these two residues are involved in more hydrophobic interactions with CaM than any other residues of the peptide (see Figure 8), it seems likely that this feature of the sequence can be used to align the CaM binding sequences listed in Figure 9, thereby permitting one to predict their interaction with CaM. It is clear from this alignment that the pattern of hydrophobic and hydrophilic residues is, in general, comparable for the various peptides, suggesting that the mode of binding and the structure of the corresponding complexes with Ca^{2+} -CaM are also likely to be similar. For example, there is, in general, conservation of hydrophobic residues at the positions equivalent to Phe8 which interacts with the C-terminal domain and Val11 which interacts with both domains (see Figures 7 and 8). In addition, there are no acidic residues present which would result in unfavorable electrostatic interactions with the negatively charged Glu residues on the surface of CaM (see Figure 7). The minimum length of peptide required for high affinity binding to Ca^{2+} -CaM is defined by the 14 residue mastaporans which comprise the two hydrophobic residues at the N- and C-termini (Figure 9) and have approximately the same equilibrium association constant ($K_{\text{ass}} \approx 1-3 \times 10^9 \text{ M}^{-1}$) as M13.⁶⁵ This structural alignment also predicts that a peptide stopping just short of the second hydrophobic residue of the pair (i.e. the residue equivalent to Phe17) would only bind to the C-terminal domain and that the resulting complex would therefore retain the dumb-bell shape of Ca^{2+} -CaM. This is exactly what has been observed by small angle X-ray scattering using two synthetic peptides, C24 W and C20 W (Figure 9), comprising different portions of the CaM binding domain of the plasma membrane Ca^{2+} pump.⁶⁶ The complex with the C24 W peptide which corresponds to residues 1–24 of M13 and contains a Trp at position 4 and a Val at position 17, has a globular shape similar to that of Ca^{2+} -CaM–M13. The complex with the C20 W peptide, on the other hand, which corresponds to residues –4 to 16 of M13 and therefore lacks the C-terminal hydrophobic residue of the pair, retains the dumb-bell shape of Ca^{2+} -CaM, suggesting that the peptide only binds to the C-terminal domain.

Thus the solution structure of the complex of Ca^{2+} -CaM with M13 reveals an unusual binding mode in which the target peptide is sequestered into a hydrophobic channel formed by the two domains of CaM with interactions involving 19 residues of the target peptide (i.e. residues 3–21 of M13). In addition, a key requirement appears to be the presence of two long-chain hydrophobic or aromatic residues separated by 12 residues in order to anchor the peptide to the two domains of CaM (Figure 7). By analogy, the rope (i.e. the CaM binding domain of the target) has to be long enough and have two knots at each end for the two hands (i.e. domains) of CaM to grip it. This particular mode of binding is therefore only likely to occur if the CaM binding site is located either at an easily accessible C- or N-terminus or in a long exposed surface loop of the target protein. An example of the former is myosin light chain kinase and of the latter is calcineurin, and, in accordance with their location, the CaM binding sites are susceptible to proteolysis.^{63,67} Clearly, other types of complex between Ca^{2+} -CaM and its target proteins are possible, given the inherent flexibility of the central helix. For example, in the case of the γ -subunit of phosphorylase kinase, it appears that there are two discontinuous CaM binding sites which are capable of binding to Ca^{2+} -CaM simultaneously,⁶⁸ and

binding of a peptide derived from one of these sites causes elongation rather than contraction of Ca^{2+} -CaM,⁶⁹ indicating that the complex is of a quite different structural nature. Similarly, in the case of cyclic nucleotide phosphodiesterase⁷⁰ and CaM kinase II,⁷¹ the CaM binding sequences do not have the same spacing of hydrophobic residues seen in M13 and the other sequences listed in Figure 13 (see below) and, in addition, CaM kinase II is not susceptible to proteolysis in the absence of phosphorylation,⁷² suggesting that the mode of binding is different again. Thus, in all likelihood, the complexes of Ca^{2+} -CaM with target peptides from skeletal and smooth muscle myosin light chain kinase represent one of a range of Ca^{2+} -CaM binding modes achieving CaM–target protein interactions in an efficient and elegant manner.

5.2 The Structure of the Specific Complex of the Transcription Factor GATA-1 with DNA

The erythroid specific transcription factor GATA-1 is responsible for the regulation of transcription of erythroid-expressed genes and is an essential component required for the generation of the erythroid lineage.⁷³ GATA-1 binds specifically as a monomer to the asymmetric consensus target sequence (T/A)GATA(A/G) found in the *cis*-regulatory elements of all globin genes and most other erythroid specific genes that have been examined.⁷⁴ GATA-1 was the first member of a family of proteins, which now includes regulatory proteins expressed in other cell lineages, characterized by their recognition of the GATA DNA sequence and by the presence of two metal binding regions of the form Cys-X-X-Cys-(X)₁₇-Cys-X-X-Cys separated by 29 residues. Mutation and deletion studies on GATA-1 have indicated that the N-terminal metal binding region is not required for specific DNA binding,⁷⁵ and studies with synthetic peptides have demonstrated conclusively that a 59 residue fragment (residues 158–216 of chicken GATA-1) comprising the C-terminal metal binding region complexed to zinc and 28 residues C-terminal to the last Cys constitutes the minimal unit required for specific binding ($K_{\text{ass}} \approx 1.2 \times 10^8 \text{ M}^{-1}$).⁷⁶ In order to understand the mechanism of specific DNA recognition by GATA-1 we set out to solve the solution structure of the specific complex of a 66 residue fragment (residues 158–223) comprising the DNA binding domain of chicken GATA-1 (cGATA-1) with a 16 base pair oligonucleotide containing the target sequence AGATAA, by means of multidimensional heteronuclear filtered and separated NMR spectroscopy.⁸

The structure calculations were based on a total of 1772 experimental NMR restraints, including 117 intermolecular interproton distance restraints between the protein and the DNA. A stereoview of a best-fit superposition of 30 calculated structures (residues 2–59 of the protein and base pairs 6 to 13 of the DNA) is shown in Figure 10. The N-terminus (residue 1) and C-terminus (residues 60–66) of the protein are disordered. Base pairs 6 to 13 of the DNA are in contact with the cGATA-1 DNA binding domain and are well defined both locally and globally. The orientation, however, of the first five and last three base pairs of the DNA, which are not in contact with the protein, is poorly defined with respect to the core of the complex, although the conformation of each of these bases at a local level is reasonably well defined. This is due to the fact that, in addition to their approximate

Figure 10 Stereoview showing a superposition of the 30 simulated annealing structures of the specific complex of the DNA binding domain of cGATA-1 with DNA calculated on the basis of the experimental NMR data derived from three- and four-dimensional heteronuclear NMR spectroscopy. The backbone (N, C α , and C) atoms of cGATA-1 are shown in red and all the non-hydrogen atoms of the DNA in blue. The restrained regularized mean structure of the complex is highlighted. The coordinates are from Omichinski et al.⁸ (PDB accession code 1GAT). (Adapted from J. G. Omichinski, G. M. Clore, O. Schaad, G. Felsenfeld, C. Trainor, E. Appella, S. J. Stahl, and A. M. Gronenborn, *Science*, 1993, **261**, 438)

nature, the interproton distance restraints within the DNA are solely sequential. Hence, they are inadequate to ascertain the relative orientation of base pairs separated by more than 5–6 steps with any great degree of precision and accuracy. The global conformation of the central eight base pairs, on the other hand, is determined not only by the restraints within the DNA, but more importantly by the large number of intermolecular interproton distance restraints between the protein and DNA. The atomic rms distribution of the 30 SA structures about the mean coordinate positions for the complex proper (i.e. residues 2–59 of the protein and base pairs 6–13 of the DNA) is 0.070 ± 0.013 and 0.113 ± 0.008 nm for protein backbone plus DNA and all protein atoms plus DNA, respectively.

The protein can be divided into two modules: the protein core which consists of residues 2–51 and contains the zinc coordination site, and an extended C-terminal tail (residues 52–59).

A schematic ribbon drawing of the core is presented in Figure 11(a). The core starts out with a turn (residues 2–5), followed by two short irregular antiparallel β -sheets, a helix (residues 28–38) and a long loop (residues 39–51) which includes a helical turn (residues 44–47), as well as an Ω like loop (residues 47–51). β -strands 1 (residues 5–7) and 2 (residues 11–14) form the first β -sheet, while β -strands 3 (residues 18–21) and 4 (residues 24–27) form the second β -sheet.

Part of the core of the cGATA-1 DNA binding domain is structurally similar to that of the N-terminal zinc containing module of the DNA binding domain of the glucocorticoid receptor.⁷⁷ Thus the C α atoms of 30 residues of these two proteins can be superimposed with an rms difference of only 0.14 nm Figure 11(b). Apart from the four Cys residues that coordinate the zinc atom, only 1 residue (Lys36 in the cGATA-1 DNA binding domain and Lys465 in the glucocorticoid receptor) is conserved between the two proteins. The structural similarity extends from the N-terminus up to the end of the helix (residues 3–39 of the cGATA-1 DNA binding domain and residues 436 to 468 of the glucocorticoid receptor), and

the Zn–S γ geometry, as well as the side-chain conformations of the four coordinating cysteines, are identical. The loop between strands β 2 and β 3 has three deletions, and the turn between strands β 3 and β 4 has one deletion in the glucocorticoid receptor with respect to cGATA-1. The topology and polypeptide trace following the carboxyl end of the helix, however, are entirely different in the two proteins. Thus, in the DNA binding domain of the glucocorticoid receptor there is a second compact zinc containing module (residues 470–514) made up of two strands and two helices, while in the cGATA-1 DNA binding domain there is a long loop (residues 38–51) and extended strand (residues 52–59).

The overall topology and structural organization of the complex is shown in Figures 12(a) and 12(b). The conformation of the oligonucleotide is of B type. The helix and the loop connecting strands β 2 and β 3 (which is located directly beneath the helix) are located in the major groove, while the C-terminal tail wraps around the DNA and lies in the minor groove, directly opposite the helix. The overall appearance is analogous to that of a right hand holding a rope, with the rope representing the DNA, the palm and fingers of the hand the core of the protein, and the thumb the C-terminal tail. It is this pincer-like configuration of the protein that causes a small 10° kink in the DNA. The long axis of the helix lies at an angle of about 40° to the base planes of the DNA [Figure 12(a)], while the C-terminal tail is approximately parallel to the base planes [Figure 12(b)].

Views of side-chain contacts with the DNA in the major and minor grooves are shown in Figures 12(c) and 12(d), respectively, while a schematic representation of all the contacts is provided in Figure 13. The cGATA-1 DNA binding domain makes specific contacts with eight bases, seven in the major groove (A6, G7, A8, T25, A24, T23, and T22) and one in the minor groove (T9). All the base contacts in the major groove involve the helix and the loop connecting β -strands 2 and 3. In contrast to other DNA binding proteins, the majority of base contacts involve hydrophobic interactions. Thus, Leu17 interacts with A6, G7, and T25; Thr16 with A24 and T25; Leu33 with A24 and T23; and Leu37 with T23 and T22. This accounts for the predominance of thymidines in the DNA target site. Indeed, there are only three hydrogen-bonding interactions: namely, between the side chain of Asn29 and the N-6 atoms of A24 and A8 in the major groove, and between the N ζ H $_3^+$ of Lys57 and the O-2 atom of T9 in the minor groove. In this regard, it is interesting to note that there is a reduction of 11.27 nm² in the surface accessible area of the cGATA-1 DNA binding domain in the presence of DNA (corresponding to a 20% decrease in the accessible surface), and a decrease in the calculated solvation free energy of folding⁵³ of 13 kcal mol⁻¹ (54 kJ mol⁻¹). This latter effect can clearly make a sizable contribution to the specific binding constant ($K_{\text{ass}} \approx 1.2 \times 10^8$ M⁻¹).

The remaining contacts involve the sugar–phosphate backbone, the majority of which are located on the second strand (that is G20 to T27). Salt bridges and/or hydrogen bonds with the phosphates of G7, A24, and T22 are made by Arg19, Arg47, and His38, respectively, in the major groove, and with the phosphates of C13, T25, C26 and T27 by Arg54, Thr53, Arg56, and Ser59, respectively, in the minor groove. The interactions of Arg54, and Arg56 above and below the polypeptide chain span the full length of the target site and are probably responsible for the bending of the DNA in the direction of the

Figure 11 (a) Schematic ribbon drawing of the core of the cGATA-1 DNA binding domain. (b) Superposition of the C α atoms of the cGATA-1 (green) and glucocorticoid receptor (red) DNA binding domains. The zinc and coordinating cysteines are shown in yellow for cGATA-1 and in purple for the glucocorticoid receptor; the residues are labeled according to the numbering in cGATA-1. The alignment of cGATA-1 with the glucocorticoid receptor is as follows: residues 3–13, 18–21, 25–39, and 46 of cGATA-1 are superimposed on residues 436–446, 448–451, 454–468, and 490, respectively, of the glucocorticoid receptor with a C α atomic rms of 0.14 nm. The diagram in (a) was made using the program MOLSCRIPT.¹⁰² The coordinates of the glucocorticoid receptor DNA binding domain shown in (b) are taken from Luisi et al.⁷⁹ The cGATA-1 coordinates are from Omichinski et al.⁸ (PDB accession code 1GAT). (Adapted from J. G. Omichinski, G. M. Clore, O. Schaad, G. Felsenfeld, C. Trainor, E. Appella, S.J. Stahl, and A. M. Gronenborn, *Science*, 1993, **261**, 438)

minor groove. Likewise, all the sugar contacts involve the second strand. In the major groove they are hydrophobic in nature, and involve contacts between the sugars of T22, T23 and A24 with Tyr34, Leu33 and Ala30, and Ile51 and Thr16, respectively. In the minor groove, hydrophobic sugar DNA–protein interactions are made by C-13 with the aliphatic portion of the side chain of Arg54, T23 and T24 with Gln52, T25 and C26 with the aliphatic portion of the side chain of Arg 56, and C26 with Ser59. In addition, there is a hydrogen bond between the side-chain amide of Gln52 and the sugar O-3' atom of T23.

The mode of specific DNA binding protein that is revealed in this structure is distinct from that observed for the other three classes of zinc containing DNA binding domains whose structures have previously been solved.^{77–82} Features specific to the complex with the DNA binding domain of cGATA-1 include: the relatively small size of the DNA target site (eight base pairs of which only a contiguous stretch of six is involved in specific contacts); the monomeric nature of the complex in which only a single zinc binding module is required for specific binding; the predominance of hydrophobic interactions involved in specific base contacts in the major groove; the presence of a basic C-terminal tail which interacts with the DNA in the minor groove and constitutes a key component of specificity; and, finally, the pincer-like nature

of the complex in which the core and tail subdomains are opposed and surround the DNA just like a hand gripping a rope. The structure of the cGATA-1 DNA binding domain reveals a modular design. The fold of residues 3–39 is similar to that of the N-terminal zinc binding module of the DNA binding domain of the glucocorticoid receptor, although, with the exception of the four Cys residues that coordinate zinc, there is no significant sequence identity between these regions of the two proteins. Residues 40–66 are part of a separate structural motif. In this regard it is interesting to note that, in addition to both zinc binding modules being encoded on separate exons in the cGATA-1 gene (exons 4 and 5), the next intron/exon boundary lies between amino acids 39 and 40 (current numbering scheme) of the DNA binding domain, thereby separating the C-terminal zinc binding domain from the basic tail⁸³.

5.3 Hydration of the Specific Complex of the Transcription Factor GATA-1 with DNA

A number of recent high resolution crystal structures of protein–DNA complexes have suggested that bound water may play an important role in the recognition process in the

Figure 12 (a, b) Schematic ribbon drawings illustrating the interactions of cGATA-1 with DNA. (c, d) Side-chain interactions between cGATA-1 and the DNA in the major and minor grooves, respectively. The protein backbone is shown in green and the protein side chains in yellow; the color code for the DNA bases is as follows: red for A, lilac for T, dark blue for G, and light blue for C. The diagrams were made using the program VISP.¹⁰³ The coordinates of the cGATA-1–DNA complex are from Omichinski et al.⁸ (PDB accession code 1GAT). (Adapted from J. G. Omichinski, G. M. Clore, O. Schaad, G. Felsenfeld, C. Trainor, E. Appella, S. J. Stahl, and A. M. Gronenborn, *Science*, 1993, **261**, 438)

form of indirect read-out in which the bound water molecules serve to bridge hydrogen bonds between functional groups on the protein and the DNA bases.^{84–86} In addition, a bound water molecule has been detected at the interface of the complex between the *Antp*(C39 S) homeodomain and a 14-base pair duplex in solution using NMR spectroscopy.⁸⁷ In contrast to other protein–DNA complexes, in which the majority of specific interactions involve hydrogen bonds between the protein and the DNA bases, the structure of the specific complex of GATA-1 with DNA, as indicated in the previous section, suggests that hydrophobic effects constitute a large proportion of the specific binding energy.⁸ This would predict that water of hydration would be excluded from the interface between GATA-1 and the DNA bases in the major groove, but would be present at the interface between GATA-1 and the

sugar–phosphate backbone, as well as at the solvent exposed surface of the protein. To test this hypothesis we carried out selective two-dimensional H₂O NOE and H₂O rotating frame Overhauser effect (ROE) ¹H–¹⁵N and ¹H–¹³C heteronuclear single quantum correlation experiments⁸⁸ to detect through space (<0.4 nm) contacts between bound water and protons of the protein, thereby identifying the location of bound water molecules in the specific complex of chicken GATA-1 with DNA.⁸⁹

A number of water molecules could be detected between the protein and the phosphate backbone, as well as at the solvent exposed surface of the protein. However, no water molecules could be observed at the interface of the protein with the bases of the DNA. With only one exception, the bound water molecules have a residency time greater than 200–300 ps. On

Figure 13 Schematic diagram summarizing the contacts between cGATA-1 and DNA. The DNA is represented as a cylindrical projection. Bases interacting with the protein are shaded; phosphates are represented as circles; circles with hatches directed towards the right and left indicate sites of interaction with sugar or phosphate or both in the major and minor grooves, respectively. (Adapted from J. G. Omichinski, G. M. Clore, O. Schaad, G. Felsenfeld, C. Trainor, E. Appella, S. J. Stahl, and A. M. Gronenborn, *Science*, 1993, **261**, 438)

the basis of the structure of the complex of GATA-1 with DNA,⁸ we were able to identify unambiguously 17 methyl protons and 3 backbone NH protons in close proximity to bound water.⁸⁹ The location of the protein residues near bound water are indicated in the structure of the complex of GATA-1 with DNA shown in Figure 14.

An approximate estimate of the residency times of these bound water molecules can be obtained from the sign of the NOE.^{9,90} If a water molecule is bound to a macromolecule with a correlation time in the spin diffusion limit (i.e. greater than about 2 ns), the NOE between water and a protein proton will be zero for a residency time of about 300 ps, while for residency times smaller and longer than 300 ps the NOE will be positive and negative, respectively. In contrast, the ROE remains positive for all residency and correlation times. The NH protons of Ala30, Tyr34, and Tyr35 and the methyl groups of Ala3, Ala30, Met46, and Ile51 (γ_m and δ_m) exhibited negative NOEs to water, indicating a residency time greater than about 500 ps. The methyl protons of Met23 exhibited a positive NOE to water, indicative of a residency time of 100–300 ps. For the remaining surface methyl protons, the NOEs (at a mixing time of 60 ms) to water were too weak to

observe and only ROEs were seen, indicating residency times in the range 200–500 ps.

All methyl groups that are exposed to solvent are associated with bound water molecules. These include Ala3, Val6 (γ_1 and γ_2), Leu17 (δ_2 only), Met23, Val40 (γ_1 and γ_2), Leu44 (δ_1 and δ_2), and Val58 (γ_1 and γ_2). Bound water molecules in contact with exposed hydrophobic surfaces are rarely seen in protein crystal structures as the water molecules are only well ordered (high occupancy and low thermal factor) if the protein donates anchor points in suitable hydrogen-bonding positions.⁹¹ In the absence of hydrogen bonding, low occupancies and high thermal B factors render such water molecules unobservable.⁹¹ Indeed, there is only one crystallographic example where water surrounding an exposed hydrophobic group has been seen in the absence of hydrogen bonding, namely the water pentagons surrounding Leu18 in the 0.088 nm resolution crystal structure of crambin.⁹² In contrast to the crystallographic case, bound water can be readily detected by NMR over a very wide range of residency times (with a lower limit of 50–100 ps) and is not eliminated by rapid independent rotation of a water pentagon around a rotating methyl group. Moreover, the NMR experiment is not dependent on uniform ordering insofar as the bound water could be in somewhat different positions

Figure 14 Stereoview of the solution structure of the specific complex of GATA-1 and DNA, illustrating the location of groups in close proximity to bound water. The DNA is displayed in blue, the protein backbone in red, and the side chains in close proximity to bound water detected in the H_2O ROE/NOE HSQC (heteronuclear single quantum correlation) experiments in green. The side chain of Leu33 which interacts directly with the bases of the DNA in the major groove and is not close to bound water is shown in orange. In the case of Leu17, only the surface exposed $\text{C}^{\delta 2}\text{H}_3$ methyl group gives rise to a ROE with bound water; the $\text{C}^{\delta 1}\text{H}_3$ methyl group which interacts directly with the DNA bases is not close to bound water. The model is taken from the solution NMR structure given by Omichinski et al.⁸ (PDB accession number 1GAT) and was generated using the program VISIP.¹⁰³ (Adapted from G. M. Clore, A. Bax, J. G. Omichinski, and A. M. Gronenborn, *Structure*, 1994, 2, 89)

in different molecules. In the X-ray diffraction experiment, on the other hand, bound water could only be detected if it occupied the same position in different protein molecules; that is to say there has to be uniform ordering of the bound water throughout the protein molecules of the crystal. Consequently, rapid rotation of a water pentagon about a methyl group, in the absence of discrete hopping, would result in smearing of the electron density beyond the limit of detectability.

The ubiquitous presence of bound water molecules close to exposed hydrophobic groups observed by NMR is completely consistent with the thermodynamic results of Privalov and Makhatadze,^{93,94} who showed that the hydration of methyl groups is associated with a large negative entropy ($-40.3 \text{ J mol}^{-1} \text{ K}^{-1}$), a negative enthalpy ($-8.28 \text{ kJ mol}^{-1}$) and only a small positive Gibbs free energy (3.72 kJ mol^{-1}). Indeed, the entropy of hydration of methyl groups is comparable to that of polar groups (-41 to $-50 \text{ J mol}^{-1} \text{ K}^{-1}$), indicating that their ordering power for water is comparable.

All methyl groups that are in close proximity to the phosphodiester backbone but do not interact with the bases are also associated with bound water molecules. In these cases, it is clear that the water is stabilized by hydrogen bonding interactions with either the phosphate group or the O-5' and O-3' oxygen atoms. Interestingly, similarly located water molecules have also been observed in crystal structures of DNA–protein complexes.^{95,96} The results on the specific complex of GATA-1 with DNA indicate the presence of a cluster of water molecules in the vicinity of the sugar–phosphate backbone of T22, T23, A24, and T25. It is important to note, however, that these interactions do not confer specificity. In the minor groove there is a bound water molecule(s) between the $\text{C}^{\epsilon}\text{H}_3$ of Met46, the sugar of T22 and the phosphate of T23. In the major groove, four clusters of bound water molecules are observed: namely between the $\text{C}^{\delta 2}\text{H}_3$ methyl group of Leu37 and the sugar and phosphate of T22; between the $\text{C}^{\delta 1}\text{H}_3$ of Leu37, the backbone NH protons

of Tyr34 and Tyr35, and the phosphate of T23; between the methyl group of Ala30, the NH proton of Ala30, and the phosphate of A24; and finally between the $\text{C}^{\gamma}\text{H}_3$ and $\text{C}^{\delta}\text{H}_3$ methyl groups of Ile51, the sugar of A24 and the phosphate of T25. In all likelihood, the water molecule(s) associated with the NH protons Tyr34 and Tyr35, and with the NH proton of Ala30, participate in bridging hydrogen bonds between the relevant amide group of the protein and the sugar–phosphate backbone of the DNA.

In contrast to the above methyl groups, no NOEs or ROEs to water were observed for either of the two Leu33 methyl groups or the $\text{C}^{\delta 1}\text{H}_3$ methyl group of Leu17, all of which are involved in hydrophobic interactions with the bases.⁸ This indicates that water is excluded from the interface between the protein and the DNA bases in the major groove. In addition, complementary conventional two-dimensional ^1H – ^1H NOE experiments with ^{12}C filtering failed to detect any bound water close to the thymine methyl groups of the DNA, providing further evidence for the exclusion of water at the interface of the protein and the DNA bases. The absence of water at the interface between the protein and the DNA bases in the major groove lends further credence to the importance of hydrophobic interactions in stabilizing the specific interaction between chicken GATA-1 and DNA, and indicates that hydrophobic interactions can play an important role in protein–DNA recognition and specificity.

6 CONCLUDING REMARKS

From the examples presented in this article it should be clear that the recent development of a whole range of highly sensitive multidimensional heteronuclear edited and filtered NMR experiments has revolutionized the field of protein structure determination by NMR. Proteins and protein–ligand complexes in the 15–25 kDa range are now amenable to detailed

structure analysis in solution. Moreover, the potential of the current methods can probably be extended to systems even up to 40 kDa, providing that they are very well behaved from an NMR perspective. Nevertheless, despite these advances, it should always be borne in mind that there are a number of key requirements that have to be satisfied to permit a successful structure determination of larger proteins and protein complexes by NMR. The protein in hand must be soluble and should not aggregate up to concentrations of about 1 mM, it must be stable at room temperature or slightly higher for many weeks, it should not exhibit significant conformational heterogeneity that could result in extensive line broadening, and finally it must be amenable to uniform ^{15}N and ^{13}C labeling. At the present time there are only a few examples in the literature of proteins in the 15–25 kDa range that have been solved by means of multidimensional heteronuclear NMR spectroscopy. In addition to the three examples presented here, only the structures of interleukin-4,^{33,97,98} glucose permease IIA,⁹⁹ the complex of cyclophilin with cyclosporin,¹⁰⁰ and the *Antennapedia* homeodomain-DNA complex¹⁰¹ have been published. It is hoped that over the next few years, the widespread use of these multidimensional heteronuclear experiments coupled with semiautomated assignment procedures will result in many more NMR structures of such larger proteins and protein-ligand complexes.

Acknowledgments

We thank our many colleagues, past and present, who have contributed to the work carried out in our laboratory. Above all, we thank Ad Bax with whom we have shared numerous stimulating discussions, fruitful experiments, and a continuous and most enjoyable collaboration in the best of scientific spirits. This work was supported in part by

the AIDS Targeted Anti-Viral Program of the Office of the Director of the National Institutes of Health. This article is adapted from two reviews: *Protein Science*, 1994, **3**, 372, and *Progress in Biophysical and Molecular Biology*, 1994, **62**, 153..

Biographical Sketches

G. Marius Clore. *b* 1955. B.Sc. University College London, 1976; M.D., University College Hospital Medical School, London, 1979; Ph.D., National Institute for Medical Research, London, 1982. Scientific staff, National Institute for Medical Research, London, 1980–1984; Joint Head, Biological NMR Group, Max-Planck Institute for Biochemistry, Martinsried, West Germany 1984–1988; Chief, Section of Protein

NMR, Laboratory of Chemical Physics, National Institutes of Health 1988 – present. Approx. 260 publications, and with A. M. Gronenborn the book ‘NMR of Proteins’. Research interests include biological NMR spectroscopy and structural biology.

Angela M. Gronenborn. *b* 1950. Dipl. Chem., 1975; Ph.D., 1978, University of Cologne; Scientific staff, National Institute for Medical Research, London, 1979–1984; Joint Head, Biological NMR Group, Max-Planck Institute for Biochemistry, Martinsried, West Germany 1984–1988; Chief, Section of Structural Biology, Laboratory of Chemical Physics, National Institutes of Health, 1988 – present. Approx. 250 publications, and with G. M. Clore the book ‘NMR of Proteins’. Research interests include biological NMR spectroscopy and structural biology.

Detailed mechanisms by which CaM regulates the activity of target enzymes and proteins are still not yet fully understood even for a single case. Nevertheless, NMR spectroscopy has contributed tremendously to our understanding of the structural basis of the action of CaM in the context of interactions with

Ca^{2+} , and peptides and drugs. In the following discussion NMR studies on CaM reported during the period of 1979–93 will be summarized.

2 INTERACTIONS WITH METAL IONS AND DRUGS

The first 250- and 360-MHz ^1H NMR spectra of bovine brain CaM were reported by Seamon^{17,18} in 1979 and 1980, who demonstrated that dramatic Ca^{2+} -dependent spectral changes could be monitored by ^1H NMR. Aromatic proton resonances of Tyr-99, His-107, and Tyr-138, and a unique trimethyl group of ϵ -trimethylated Lys-115 were identified. Klevit et al.¹⁹ and Krebs and Carafoli²⁰ studied the interaction of bovine brain CaM with TFP using ^1H NMR. Shimizu et al.^{21,22}

used ^{19}F NMR to study the interactions of porcine brain and *Tetraphymena pyriformis* CaM with TFP. All these studies indicate that one CaM molecule binds two TFP molecules.

More detailed assignments for aromatic ring and methyl protons in scallop testis CaM were reported by Ikura et al.²³ in 1983. Using those resonance assignments, Ca^{2+} -induced conformational changes have been examined.²⁴ Figure 3 illustrates Ca^{2+} -induced changes in the aromatic region of the ^1H NMR spectra. The results show that many resonances C-terminal domain (Phe-99, His-107, trimethyl Lys-115, and Tyr-138) are shifted in an early stage of Ca^{2+} titration (0–2 mol Ca^{2+} per mol of CaM), thus concluding that the C-terminal domain contains the high affinity sites for Ca^{2+} . Forsén and co-workers independently reached the same conclusion from ^{43}Ca and ^{113}Cd NMR studies^{25,26} using two tryptic fragments

Figure 2 Ribbon diagram representations of (a) Ca^{2+} -CaM¹¹ and (b) the Ca^{2+} -CaM-M13 complex¹⁴ as generated by the program ribbons. The CaM N-terminal domain is shown in blue and the C-terminal domain in red. In Figure 2(b), the structure is viewed parallel to the M13 peptide helix axis

of CaM (TR₁C, fragment 1–75; TR₂C, fragment 78–148). These half-fragments were found to be extremely useful for NMR studies of CaM. In 1984, ¹H NMR studies on the half-fragments were reported by three groups^{27–30} almost at the same time. Two uniquely low-frequency shifted ring proton resonances at 6.46 and 6.50 ppm of apo-CaM were assigned to phenylalanines in the N-terminal domain. All these studies provided further evidence for the order of Ca^{2+} binding to four sites in CaM. Together with ⁴³Ca and ¹¹³Cd NMR^{25,26} and other biophysical studies,^{4,5,8} it became clear that the two tryptic half-fragments retain the conformations which they assume in whole CaM. The property was shown for both the Ca^{2+} -free and Ca^{2+} -bound forms.

Because of the complexity of the ¹H NMR spectra of whole CaM, several groups used the tryptic half-fragments to elucidate the structural details of CaM. In 1984, Aulabaugh et al.³¹ applied 2D ¹H NMR at 600 MHz to fragment TR₂C in the absence of Ca^{2+} and obtained assignments for many side-chain proton resonances to particular amino acid types. In 1985, Ikura et al.³² applied 2D ¹H NMR techniques to the TR₂C fragment both in the presence and the absence of Ca^{2+} , and obtained about 30% backbone and side-chain proton assignments in each state using the sequential assignment

procedure proposed by Wüthrich and co-workers (see *Biological Macromolecules: Structure Determination in Solution and Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). Extremely high-frequency shifted amide proton resonances (10.0–11.0 ppm) were assigned to the glycine residues at the fifth position of the Ca^{2+} -binding loops. These uniquely shifted glycine amide resonances were further characterized using both TR₁C and TR₂C fragments.³³ Such large shifts of the amide protons of this conserved glycine residues in EF-hand Ca^{2+} -binding loops were also found in troponin C³⁴ and calbindin³⁵ (see *Calcium-Binding Proteins*), suggesting that this feature is universal among the members of the EF-hand superfamily. Hoffman and Klevit³⁶ reported 2D ¹H NMR analysis of the Ca^{2+} -free TR₁C fragment in the absence of Ca^{2+} , indicating hydrophobic contacts between Phe-16 and Val-35 which are absent in the Ca^{2+} -bound form of the crystal structure.^{11,12} More recently, Finn et al.³⁷ obtained the complete backbone ¹H resonance assignments of the Ca^{2+} -free TRC fragment, indicating that the Ca^{2+} -free state retains the helix-loop-helix secondary structure similar to that observed in the Ca^{2+} -bound form.^{11,12,38}

Figure 3 The aromatic region of the 400 MHz ^1H NMR spectra of scallop testis calmodulin at various Ca^{2+} concentrations. (Reproduced by permission of the American Chemical Society from Ikura et al.²⁴)

Several different NMR techniques were used to study the kinetics of Ca^{2+} binding to CaM and its fragments. Calcium-43 and ^{113}Cd NMR studies^{25,26} indicate that the resonances from metal ions bound to sites III and IV show much slower exchange on the NMR timescale than those from metal ions bound to sites I and II. ^1H NMR saturation transfer and spectral simulation methods were employed to obtain the exchange rate constants and activation parameters between Ca^{2+} -free and Ca^{2+} -bound forms of two half-fragments.³⁹ Two distinct rate constants of $3\text{--}10\text{ s}^{-1}$ and $300\text{--}500\text{ s}^{-1}$ were found at 22°C for the C-terminal and the N-terminal fragments, respectively. All these results confirm the identification of sites III and IV as being the high affinity sites.

Starovasnik et al.⁴⁰ studied the Ca^{2+} binding and structural properties of CaM from the yeast *Saccharomyces cerevisiae* using flow dialysis and ^1H NMR. The amino acid sequence of yeast CaM is 60% identical to that of vertebrate CaM, whereas all known vertebrate CaM sequences are totally identical. The results indicate that, unlike vertebrate CaM, yeast CaM binds only three Ca^{2+} ions and that all three sites exhibit slow-exchange behavior upon Ca^{2+} binding. Thermal denaturation properties of yeast CaM as well as of its half-fragments were also studied. Starovasnik et al.⁴¹ studied a series of four site-directed mutants using the same techniques, demonstrating interactions between the Ca^{2+} -binding sites in CaM.

Vogel and co-workers have extensively studied lysine residues in CaM using ^1H and ^{13}C NMR. The pK_a values of *N*-dimethylated lysine residues were obtained both in apo and Ca^{2+} -bound forms, as well as in a complex with a 22-residue peptide comprising the CaM-binding region of skeletal muscle

MLCK.^{42,43} Zhang et al.⁴⁴ applied ^{14}N NMR to ϵ -trimethyl Lys-115 in both vertebrate and yeast CaMs. The ϵ -trimethyl group of this posttranslated lysine gives rise to a sharp ^{14}N NMR resonance because of its unique tetrahedral symmetry. Selenium-77 NMR was used to study the microenvironments of the nine methionine residues in CaM, all of which were biosynthetically substituted with selenomethionine.⁴⁵

3 CALCIUM-CALMODULIN COMPLEX

During the period 1989–93, CaM was extensively used by Bax's group at the NIH to develop multidimensional heteronuclear MR methods (see *Multidimensional Spectroscopy: Concepts, and Three- and Four-Dimensional Heteronuclear Magnetic Resonance*). This methodology requires isotope enrichment of proteins with ^{15}N and ^{13}C . Uniformly ^{15}N - and ^{13}C -labeled CaM was obtained using an *E. coli* expression system.⁴⁶ Figure 4 shows a ^1H – ^{15}N heteronuclear single quantum coherence (HSQC) spectrum of Ca^{2+} -loaded recombinant CaM labeled uniformly with ^{15}N , illustrating that a high-quality ^1H – ^{15}N shift correlation spectrum can be obtained at 1 mM protein concentration. Ikura et al.^{38,47} reported complete backbone and side-chain ^1H , ^{13}C , and ^{15}N assignments of Ca^{2+} -loaded recombinant *Drosophila* CaM using a series of triple- and double-resonance 3D and 4D experiments. The secondary structure in solution was then characterized using NOE, $^3J_{\text{NH}\alpha}$ coupling constants, and ^{13}C chemical shift data.³⁸ These results confirm the crystal structure^{11,12} in that both the N- and C-terminal globular domains assume a pair of the EF-hand type helix–loop–helix motifs. However, the central helix portion (residues 65–92), found in the crystal structure, appears to contain a nonhelical region at residues 78–81 in solution. Nitrogen-15 relaxation studies reported by Barbato et al.⁴⁸ further indicate that this nonhelical portion has considerable flexibility, consistent with other studies using solution techniques such as small angle X-ray or neutron scattering.⁴⁹ The ^{15}N relaxation studies⁴⁸ (see *Protein Dynamics from NMR Relaxation*) provide additional interesting insights into the structure and dynamics of Ca^{2+} –CaM. The rotational correlation times obtained for the N- and C-terminal domain (7.1 ns and 6.3 ns, respectively) do not reflect the overall motion of a 16.7 kDa protein, but rather correspond to that of a smaller protein (ca. 12 kDa). Further, the correlation times for the individual amide bond vectors vary to a much lesser degree than predicted by hydrodynamic calculations for rigid dumb-bell models. These results indicate that the two domains move independently in solution.

4 CALCIUM-CALMODULIN-PEPTIDE TERNARY COMPLEXES

In 1985, Kleivit et al.⁵⁰ using ^1H NMR studied the interaction of CaM with a 26-residue synthetic peptide (known as M13) comprising the CaM-binding domain of skeletal muscle myosin light chain kinase. These data indicate that both the N- and C-terminal domains must participate in the interaction with the M13 peptide. The ^{113}Cd NMR studies of mastoparan binding to Cd_4CaM have shown that both the N- and C-terminal domains undergo conformational

Figure 4 The 500 MHz ^1H - ^{15}N HSQC shift correlation spectrum of *Xenopus laevis* calmodulin. The spectrum was recorded using a pulse sequence combined with the pulse field gradient technique described by Kay et al.⁶⁶ The full backbone amide assignment of *Xenopus* calmodulin is available from the author

changes upon binding of the peptide (see **Calcium-Binding Proteins**). Seeholzer et al.⁵¹ also used ¹H NMR to study the interaction of melittin with [¹H]- and [²H]-CaM, suggesting that melittin assumes an α -helical conformation upon binding CaM, consistent with earlier conclusions based on circular dichroism spectra. Yazawa et al.,⁵² using the ¹H NMR signal of His-107, showed that in the presence of M13 the Ca²⁺-dependent conformational change becomes completely cooperative between the N- and C-terminal domains. Ikura et al.⁵³ studied the Cd²⁺ dependence of the interactions of CaM with M13 and mastoparan using ¹¹³Cd NMR, supporting the notion of the higher cooperativity of metal binding in the presence of these peptides. Ohki et al.^{54,55} studied the interaction of mastoparan with CaM under various solution conditions using ¹H NMR. It was shown that the N-terminal domain may interact with a second mastoparan molecule with a lower affinity, and that Mg²⁺ reduces the cooperative Ca²⁺ binding to CaM in the presence of mastoparan.

In 1991, Ikura et al.⁵⁶ completed ¹H, ¹³C, and ¹⁵N backbone assignments of Ca²⁺-CaM complexed with M13 by using multidimensional heteronuclear MR methods. Proton assignments of M13 in the complex were also obtained using ¹⁵N/¹³C-filtered techniques⁵⁷ (see **Half-Filter Experiments: Proton-Carbon-13**). Based on these assignments, the three-dimensional NMR structure of the Ca²⁺-CaM-M13 ternary complex was determined.¹⁴ Figure 2(b) shows a schematic ribbon model of the restrained minimized mean structure. A striking difference in conformation can be seen as compared with the crystal structure of Ca²⁺-CaM¹¹ [Figure 2(a)]. The N- and C-terminal domains of CaM (residues 6–73 and 83–146) remain essentially unchanged upon complexation. The long central helix, (residues 65–93), however, which connects the two domains in the crystal structure of Ca²⁺-CaM [Figure 4(a)], is disrupted into two helices connected by a long flexible loop (residues 74–82), thereby enabling the two domains to clamp residues 3–21 of the bound peptide which adopt a helical conformation. Key residues of the peptide are Trp-4 and Phe-17, which serve to anchor the N- and C-terminal halves of the peptide to the C- and N-terminal domains of CaM, respectively. This characteristic structure of Ca²⁺-CaM complexed with the M13 peptide was confirmed by a crystallographic study on Ca²⁺-CaM complexed with a similar peptide derived from smooth muscle MLCK.¹⁵ Based on the knowledge of the structural features of these Ca²⁺-CaM-peptide complexes, Prumb et al.⁵⁸ produced a hybrid CaM-peptide molecule and characterized the structural and Ca²⁺-binding properties using ¹H–¹⁵N HSQC and flow dialysis experiments.

Roth et al.^{59,60} revealed the secondary structure of a 19-residue smooth muscle MLCK peptide and CaM in their complex using heteronuclear multidimensional NMR techniques. Most of the backbone amide nitrogen nuclei in the MLCK peptide were labeled with ¹⁵N, which allowed the characterization of the α -helix structure of the peptide. Precheur et al.⁶¹ also used a similar labeling technique on a 17-residue model peptide proposed by DeGrado et al.,⁶² and showed a stable α -helical structure in the N-terminal 11 residues of the complex. Zhang et al.,^{63,64} using 2D ¹H NMR, studied three synthetic CaM binding peptides which are derived from skeletal muscle MLCK, rat cerebellar nitric oxide synthase, and smooth muscle caldesmon. The MLCK⁶³ and caldesmon⁶⁴ peptides were found to assume an α -helical conformation in an aqueous trifluoroethanol mixture

(75%/25%) The nitric oxide synthase peptide⁶⁶ also adopts an α -helical structure in aqueous solution at pH 5.5 and 5 °C.

In summary, CaM has provided an excellent example of the power of the high-resolution multinuclear magnetic resonance approach. Various NMR studies have provided valuable information on the structural and physical properties of CaM as a Ca²⁺-sensitive molecular switch in cells. Yet, further studies have to come in order to elucidate secrets involved in multitarget recognition of this amazing molecule.

1 INTRODUCTION

The effects of chemical exchange, including transverse relaxation and magnetization transfer, have long been of interest in NMR spectroscopy (see **Chemical Exchange Effects on Spectra**, Volume 2 and **Relaxation Effects of Chemical Exchange**, Volume 6). Exchange phenomena in solution NMR spectroscopy arise when chemical or conformational kinetic processes render the isotropic chemical shifts of nuclear spins time-dependent, either by transferring the spins between distinct sites or by altering the local magnetic environment of the spins. Kinetic processes on times scales ranging from μs to s are effective in causing chemical exchange effects. Many biological processes occur with time constants within this range, and numerous applications have been reported that utilize chemical exchange effects to characterize time-dependent processes in biological macromolecules.^{1–20}

The present article describes a subset of ZZ-exchange,^{21,22} lineshape,^{23,24} Carr–Purcell–Meiboom–Gill (CPMG),^{25,26} and $R_{1\rho}$ ^{27,28} relaxation techniques that are sensitive to molecular motions or chemical kinetic processes on μs – s time scales in biological macromolecules. The experimental techniques, rather than specific applications, will be emphasized. In most cases, pulse sequences suitable for application to isolated $I_n\text{S}$ ($I = {}^1\text{H}$; $X = {}^{15}\text{N}$ or ${}^{13}\text{C}$; $n = 1, 2$, or 3) spin systems are presented. The pulse sequences shown do not

include details of solvent suppression techniques because different approaches are used for ${}^1\text{H}$, ${}^{13}\text{C}$, and ${}^{15}\text{N}$.^{29,30} Compensatory rf fields should be applied during the recycle delay to ensure that the same average rf power is deposited into the sample for all values of the relaxation period.³¹ The pulse sequences illustrated use INEPT elements for polarization transfer; in some cases, increased sensitivity can be obtained by replacing the INEPT transfers with heteronuclear cross polarization or CPMG-INEPT methods with large effective fields.^{32–34}

2 TWO-SITE CHEMICAL EXCHANGE

For simplicity, only two-site exchange will be considered. The nucleus of interest is assumed to exchange between two magnetically distinct environments A and B while the system remains at chemical equilibrium throughout the NMR experiment. Furthermore, the present article focuses on situations in which scalar coupling constants are not perturbed by the exchange process (see **Chemical Exchange Effects on Spectra**, Volume 2); consequently, the modified Bloch or McConnell equations are sufficient to describe the effect of exchange (see **Relaxation Effects of Chemical Exchange**, Volume 6). The kinetic scheme is:

in which k_1 and k_{-1} are forward and reverse rate constants and the chemical exchange rate constant, k_{ex} , is given by,

$$k_{ex} = k_1 + k_{-1} = \frac{k_1}{p_B} = \frac{k_{-1}}{p_A} \quad (2)$$

$p_A \geq 0.5$ and $p_B = 1 - p_A$ denote the equilibrium populations of equivalent nuclear spins in species A and B. Higher order chemical reactions, such as ligand binding or oligomerization, are treated by defining k_1 and k_{-1} as pseudo-first-order rate constants. The resonance frequencies in the rotating frame for spins in site A and B are Ω_A and Ω_B , respectively, in units of angular frequency, and the chemical shift difference between the two sites is $\Delta\omega = \Omega_B - \Omega_A$. The total equilibrium magnetization is M^0 , and the equilibrium longitudinal magnetization at each site is $M_A^0 = p_A M^0$ and $M_B^0 = p_B M^0$. The longitudinal relaxation rate constants of the sites in the absence of exchange (resulting from dipolar, shielding anisotropy (CSA), and quadrupolar relaxation) are R_{1A}^0 and R_{1B}^0 . The transverse relaxation rate constants of the sites in the absence of exchange are R_{2A}^0 and R_{2B}^0 .

The effect of exchange on free-precession lineshapes has been discussed in **Relaxation Effects of Chemical Exchange**, Volume 6. The relative values of k_{ex} and $\Delta\omega$ define the limits of what is commonly referred to as “fast” and “slow” exchange on the chemical shift time scale:

$$\begin{aligned} k_{ex} < \Delta\omega & \quad \text{Slow exchange} \\ k_{ex} \approx \Delta\omega & \quad \text{Intermediate exchange} \\ k_{ex} > \Delta\omega & \quad \text{Fast exchange} \end{aligned} \quad (3)$$

In the slow exchange limit, resolved lines are observed for the two sites with resonance frequencies Ω_A and Ω_B . The effect of exchange is to shift the resonance positions and broaden the lines until the lines coalesce in the intermediate exchange regime (a more exact analysis yields the result that coalescence occurs when $2(p_A p_B)^{1/2} \Delta\omega \approx k_{ex}$). In the fast exchange limit, a single averaged resonance line is observed at the population-weighted average shift, $\Omega = p_A \Omega_A + p_B \Omega_B$.

3 IDENTIFYING SPINS AFFECTED BY CHEMICAL EXCHANGE

The initial step in characterizing a kinetic process by NMR spectroscopy is identifying spins subject to chemical exchange. If p_B is sufficiently large and exchange is slow on the chemical shift time scale, then additional resonances arising from the second species are observed in the NMR spectra. These resonances usually are identified during initial efforts to obtain sequence specific resonance assignments. NOESY, ROESY, and ZZ-exchange spectroscopy, discussed below, are used to confirm that the additional resonances arise from chemical exchange processes. However, only a single set of resonances are observed in the NMR spectra if exchange is fast on the chemical shift time scale or if p_B is sufficiently low that the minor component is not observable in the slow exchange limit. In such circumstances, exchange effects are recognized by an increase in the transverse relaxation rate constant relative to the value expected for dipolar, quadrupolar and CSA interactions for the observed resonance signals:

$$R_2 = R_2^0 + R_{ex} \quad (4)$$

in which R_2^0 refers to either the relaxation rate constant for an individual site (for slow exchange) or to the population averaged relaxation rate constant (for fast exchange) and R_{ex} is the excess contribution to R_2 due to exchange.

R_2 in equation (4) can be approximated either by R_2^* , the free-precession damping constant including effects of magnetic field inhomogeneity, or by R_{2echo} , the damping constant observed for a Hahn spin echo experiment. The value of R_2^* is obtained from the resonance full-width at half-height linewidth, $\Delta\nu_{1/2}$, using $R_2^* = \Delta\nu_{1/2}/\pi$ or equivalently, from the decay of the time domain free induction decay or interferogram (in multidimensional NMR spectra).³⁵ The size of the inhomogeneity contribution to R_2^* can be estimated using spins not affected by the exchange process. The value of R_{2echo} is obtained using the sequence $t - 180^\circ - t$ incorporated into either a one-dimensional or multidimensional NMR experiment.³⁶ The 180° pulse must be selective to refocus scalar coupling interactions. If spectra are recorded for $t = 0$ and $t = \tau$, then $R_{2echo} = (2\tau)^{-1} \ln[I(0)/I(\tau)]$, in which $I(t)$ is the intensity of the resonance measured for an echo time t . The echo time, τ , should be long enough that $\tau k_{ex} \gg 1$; otherwise, the effects of exchange on the echo decay are partially suppressed. Complete expressions for the echo decay are given in **Relaxation Effects of Chemical Exchange**, Volume 6. In either approach, additional decoupling sequences may need to be applied during the free-precession evolution period or during the spin-echo delay to prevent evolution into antiphase coherences subject to additional relaxation mechanisms.^{37,38}

The value of R_2^0 is obtained by one of the following approaches: (1) analysis of R_1 , R_2 and NOE data for ^{13}C or ^{15}N spins using the model free formalism;^{39,40} (2) use of the magnetic field dependence of R_2 to determine $J(0)$, the spectral density function at zero frequency;^{41–43} and (3) use of ^1H -X dipole/X CSA relaxation interference rate constants.^{43,44}

The first method determines the rotational diffusion tensor for the molecule using R_1 , R_2 and NOE relaxation rate constants for spins not subject to conformational exchange broadening (see **Protein Dynamics from NMR Relaxation**, Volume 6). Once the diffusion tensor for the molecule is known, R_2^0 for individual exchange broadened nuclear spins is approximated using the measured values of R_1 and NOE. This method is automated in software programs such as ModelFree.³⁹ Residues subject to exchange broadening must be carefully distinguished from residues affected by rotational diffusion anisotropy in order to obtain an accurate assessment of the diffusion tensor.^{44–46}

Most investigations of molecular dynamic properties of macromolecules through spin relaxation measure R_2 using CPMG experiments with a single spin echo delay, τ_{cp} , satisfying $1/\tau_{cp} \geq 1000 \text{ s}^{-1}$ or $R_{1\rho}$ experiments with an effective field in the rotating frame, ω_e , satisfying $\omega_e \geq 12000 \text{ s}^{-1}$ to partially suppress exchange effects.⁴⁷ Under these conditions, the residual R_{ex} contribution to R_2 is proportional to B_0^2 , in which B_0 is the static magnetic field strength, for all exchange time scales.⁴⁸ Using this result, the second approach defines:^{42,43}

$$\begin{aligned} \Gamma &= R_2 - \frac{1}{2}R_1 - \left(\frac{3d^2}{4}\right)J(\omega_H) \\ &= \left(\frac{d^2}{2}\right)J(0) + \left(\frac{2}{9}\gamma_C^2\Delta\sigma^2J(0) + \Theta_{ex}\right)B_0^2 \end{aligned} \quad (5)$$

in which $d = (\mu_0 h \gamma_H \gamma_X) / (8\pi^2 r_{XH}^3)$; μ_0 is the permeability of free space; h is Planck's constant; γ_H and γ_X are the gyromagnetic ratios for ^1H and X spins, respectively; r_{XH} is the distance between the two nuclei; Θ_{ex} is a constant of proportionality; $\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp}$; and the principal components of the X spin CSA tensor are $\sigma_{\parallel}$ and $\sigma_{\perp}$. The value of $J(\omega_H)$ is obtained from the heteronuclear NOE by reduced spectral density mapping methods.⁴⁹ The value of $J(0)$ is obtained from the intercept of a linear least squares fit of Γ versus B_0^2 . Once $J(0)$ is determined, values of R_2^0 at each value of B_0 can be obtained by setting $\Theta_{ex} = 0$ in equation (5).

The third method only is applicable to nuclear spins, such as backbone amide ^{15}N spins in proteins, with substantial CSA contributions to laboratory frame relaxation. Interference between the ^1H -X dipolar and X CSA interactions constitutes an additional relaxation mechanism that is unaffected by chemical exchange (see **Relaxation Effects Involving Cross Correlation in Biomolecules**). The transverse cross-correlation relaxation rate constant, η_{xy} , represents cross-relaxation between in-phase and antiphase magnetization, while the longitudinal cross-correlation relaxation rate constant, η_z , represents cross-relaxation between longitudinal magnetization and two-spin order. For an axially symmetric chemical shift tensor, the cross-correlation rate constants are:⁵⁰

$$\begin{aligned} \eta_z &= -\sqrt{3}cdP_2(\cos\beta)J(\omega_X) \\ \eta_{xy} &= -\frac{\sqrt{3}}{6}cdP_2(\cos\beta)[4J(0) + 3J(\omega_X)] \end{aligned} \quad (6)$$

Figure 1 Identifying chemical exchange in BPTI. Shown is a graph of $R_{2echo} - R_2^0$ versus the protein sequence. Regions of pronounced chemical exchange linebroadening, for which $R_{ex} = R_{2echo} - R_2^0 \gg 0$, are evident in the vicinity of the Cys 14–Cys 38 disulfide bond

in which $c = 3^{-1/2} \gamma_X B_0 \Delta\sigma$, β is the angle between the symmetry axes of the chemical shift and dipole tensors, and $P_2(x) = (3x^2 - 1)/2$. If both η_{xy} and η_z have been measured,^{44,51} then:⁴³

$$R_2^0 = \left(R_1 - \frac{7}{4} J(\varepsilon \omega_H) \right) \frac{\eta_{xy}}{\eta_z} + \frac{13}{8} J(\xi \omega_H) \quad (7)$$

which does not require assumptions about the values of $\Delta\sigma$ and β . If only η_{xy} has been measured, but $\Delta\sigma$ and β are known, then:

$$R_2^0 = \left(\frac{3d^2 + 4c^2}{4\sqrt{3}cd P_2(\cos \beta)} \right) \eta_{xy} + \frac{13}{8} d^2 J(\xi \omega_H) \quad (8)$$

The value of ε is 0.92 in equation (7) and ξ is 0.96 in equations (7) and (8) for ^{15}N .

An example of the use of R_{2echo} and R_2^0 for detecting chemical exchange broadened backbone amide ^{15}N resonances is provided for basic pancreatic trypsin inhibitor (BPTI) in Figure 1. Values of R_{2echo} were measured using a Hahn spin-echo sequence incorporated into an in-phase ^{15}N – ^1H HSQC experiment.^{36,52} WALTZ-16 decoupling was used during the spin echo period to suppress evolution of the ^{15}N – ^1H scalar coupling interaction.⁵³ Values of R_2^0 were obtained from η_{xy} using equation (8) and η_{xy} was measured using established techniques.⁴³ Significant values of $R_{ex} = R_{2echo} - R_2^0$ are observed for residues near the Cys 14 to Cys 38 disulfide linkage.^{48,54}

4 ZZ-EXCHANGE SPECTROSCOPY

Slow chemical exchange processes can be studied by monitoring the exchange of longitudinal magnetization between sites if the population of the minor site B is large enough to generate observable resonance signals.⁵⁵ In addition, k_{ex} must not be much less than R_{1A} and R_{1B} ; otherwise, the signals decay due to relaxation faster than population transfer. Investigations of chemical exchange using ^1H NMR spectroscopy

are complicated by the coexisting transfer of magnetization through the nuclear Overhauser effect, although the opposite signs of the NOE and ROE for macromolecules can be used to approximately suppress magnetization transfer through dipolar relaxation.⁵⁶ Isotopic enrichment of macromolecules enables X-nucleus ZZ-exchange to be utilized instead of ^1H magnetization transfer. Although either exchange of longitudinal magnetization^{57,58} or two-spin order^{57,59} can be monitored, longitudinal relaxation is much slower for ^{15}N and ^{13}C spins than for ^1H spins in macromolecules; consequently, the relaxation rate constant for two-spin order is less favorable than for X-nucleus longitudinal magnetization. For biological macromolecules, X-nucleus R_1 values typically are on the order of 1 s^{-1} ; consequently, ZZ-exchange measurements are applicable to chemical exchange processes with $k_{ex} < 10^2 \text{ s}^{-1}$.

A three-dimensional ^1H –X– ^1H pulse sequence for a ZZ-exchange measurement is shown in Figure 2; as described in the figure caption, either ^1H – ^1H or X– ^1H two-dimensional pulse sequences can be derived from the three-dimensional sequence and employed if the resonances due to exchanging spins are sufficiently well-resolved.^{58,60} The evolution of longitudinal magnetization during the mixing time, t , is described by the modified Bloch or McConnell equations:⁶¹

$$\frac{d}{dt} \begin{bmatrix} \Delta M_{zA}(t) \\ \Delta M_{zB}(t) \end{bmatrix} = \begin{bmatrix} -R_{1A}^0 - p_B k_{ex} & p_A k_{ex} \\ p_B k_{ex} & -R_{1B}^0 - p_A k_{ex} \end{bmatrix} \begin{bmatrix} \Delta M_{zA}(t) \\ \Delta M_{zB}(t) \end{bmatrix} \quad (9)$$

Figure 2 Three-dimensional pulse sequence for ZZ-exchange NMR spectroscopy.⁵⁸ Narrow and wide bars depict 90° and 180° pulses respectively. All pulses are x-phase unless otherwise indicated. Decoupling during the relaxation delay to suppress heteronuclear dipole–dipole cross relaxation and dipole/CSA cross correlation can be performed using WALTZ-16⁵³ or a train of ^1H 180° pulses at 5 ms intervals. Decoupling during acquisition is achieved with the GARP sequence.⁹² Delays are $\Delta = 1/(4J_{XH})$, $t_1^a = (1 - t_1/t_{1max})\Delta$, $t_1^b = (1 - 2\Delta/t_{1max})t_1/2$, $t_1^c = \Delta + t_1/2$, t_{1max} is the maximum value of the t_1 labeling period, $t_2^a = (1 - t_2/t_{2max})\Delta$, $t_2^b = (1 - 2\Delta/t_{2max})t_2/2$, $t_2^c = \Delta + t_2/2$, t_{2max} is the maximum value of the t_2 labeling period, and t is the mixing time. A two-dimensional X– ^1H correlation spectrum is obtained by setting $t_1^a = t_1^c = \Delta$ and $t_1^b = 0$; a two-dimensional ^1H – ^1H correlation spectrum is obtained by setting $t_2^a = t_2^c = \Delta$ and $t_2^b = 0$. The phase cycle is $\phi_1 = x, -x$; $\phi_2 = 4(x), 4(-x)$; $\phi_3 = x, x, y, y, -x, -x, -y, -y$; and receiver = $x, -x, -x, x$. The gradients are used to suppress unwanted coherences and pulse imperfections.⁹³ Frequency discrimination during t_1 and t_2 is obtained by shifting the phase of ϕ_1 and ϕ_2 , respectively, and the receiver according to the States-TTPI protocol.⁹⁴ As discussed in the text, magnetization transfer during the periods a-b and c-d may need to be considered in addition to the mixing time t

in which $\Delta M_{zA}(t) = M_{zA}(t) - M_A^0$ and $\Delta M_{zB}(t) = M_{zB}(t) - M_B^0$. The solution of this equation is:

$$\begin{bmatrix} \Delta M_{zA}(t) \\ \Delta M_{zB}(t) \end{bmatrix} = \begin{bmatrix} a_{AA}(t) & a_{AB}(t) \\ a_{BA}(t) & a_{BB}(t) \end{bmatrix} \begin{bmatrix} \Delta M_{zA}(0) \\ \Delta M_{zB}(0) \end{bmatrix} \quad (10)$$

in which,

$$\begin{aligned} a_{AA}(t) &= \frac{1}{2}[(1 - \Lambda) \exp(-\lambda_- t) + (1 + \Lambda) \exp(-\lambda_+ t)] \\ a_{BB}(t) &= \frac{1}{2}[(1 + \Lambda) \exp(-\lambda_- t) + (1 - \Lambda) \exp(-\lambda_+ t)] \\ a_{AB}(t) &= \frac{k_{ex} p_A}{\lambda_+ - \lambda_-}[(\exp(-\lambda_- t) - \exp(-\lambda_+ t))] \\ a_{BA}(t) &= \frac{k_{ex} p_B}{\lambda_+ - \lambda_-}[(\exp(-\lambda_- t) - \exp(-\lambda_+ t))] \end{aligned} \quad (11)$$

and,

$$\begin{aligned} \Lambda &= \frac{R_{1A}^0 - R_{1B}^0 + k_{ex}(p_B - p_A)}{\lambda_+ - \lambda_-} \\ \lambda_{\pm} &= \frac{1}{2}\{R_{1A}^0 + R_{1B}^0 + k_{ex} \\ &\quad \pm [(R_{1A}^0 - R_{1B}^0 + k_{ex}(p_B - p_A))^2 + 4p_A p_B k_{ex}^2]^{1/2}\} \end{aligned} \quad (12)$$

Thus, the intensity of the autpeak for site A (site B) evolves as $a_{AA}(t)$ ($a_{BB}(t)$), and the crosspeak between A and B (B and A) evolves as $a_{AB}(t)$ ($a_{BA}(t)$).

Crosspeak intensity can be observed at $t = 0$ if exchange is fast enough to transfer magnetization between sites during the INEPT periods. If ^1H magnetization is frequency labeled during t_1 , then exchange effects must be considered between points a-b and c-d in Figure 2. If only X magnetization is frequency labeled, during t_2 , then exchange effects must be

Figure 3 ^{15}N ZZ-exchange data for Thr 12 of the drk SH3 domain.²⁹ $I_{ij}(t)$ is the integrated peak volume as a function of the mixing time T . (●) $I_{AA}(t) = \Delta M_{zA}(0)a_{AA}(t)$ and (■) $I_{BB}(t) = \Delta M_{zB}(0)a_{BB}(t)$ are the volumes of the autocorrelation peaks and (○) $I_{BA}(t) = \Delta M_{zA}(0)a_{BA}(t)$ and (□) $I_{AB}(t) = \Delta M_{zB}(0)a_{AB}(t)$ are the volumes of the crosspeaks. The lines are the optimized fits to equations (10)–(12). The fitted results yield $R_{1A}^0 = 2.41 \pm 0.05 \text{ s}^{-1}$, $R_{1B}^0 = 1.90 \pm 0.11 \text{ s}^{-1}$, $k_1 = 0.86 \pm 0.06 \text{ s}^{-1}$, and $k_{-1} = 0.43 \pm 0.03 \text{ s}^{-1}$. (Reproduced with permission from *Biochemistry*, 1995, **34**, 868–878. Copyright 1994 Am. Chem. Soc)

considered between points c-d in Figure 2. The effects of exchange during the INEPT periods can be approximated by including the length of the INEPT sequences, 2Δ , in the mixing time provided that $|R_{1A}^0 - R_{1B}^0| \ll k_{ex}$ and $|R_{2A}^0 - R_{2B}^0| \ll k_{ex}$ for the X nucleus and $|R_{2A}^0 - R_{2B}^0| \ll k_{ex}$ for the ^1H spin. If these conditions do not hold, then the effects of exchange during the INEPT periods must be analyzed numerically. If a three-dimensional experiment is performed, then exchange during the t_2 evolution period must be analyzed numerically unless $t_{2max}k_{ex} \ll 1$.

Two-dimensional ^{15}N ZZ-exchange experiments have been used to quantify chemical exchange between folded and unfolded forms of the drk SH3 domain.^{14,29} Typical results are shown in Figure 3. The data were analyzed using equations (10)–(12) to determine the relaxation rate constants for the folded (site A) and unfolded forms (site B) of the protein and the folding (k_{-1}) and unfolding (k_1) rate constants.

5 LINESHAPE ANALYSIS

Lineshape analysis is a classical approach for analyzing exchange processes in NMR spectroscopy.^{23,24} Applications to proteins include chemical exchange arising from folding,^{12,62,63} ligand binding,⁶⁴ and oligomerization.¹³ In each of these applications, the lineshapes can be altered by varying experimental parameters, such as temperature, ligand concentration, denaturant concentration, or protein concentration, which enables a global analysis of lineshapes to be performed as functions of the adjustable parameters. Typically, lineshape analysis is applicable to exchange processes in biological macromolecules with $k_{ex} < 10^4 \text{ s}^{-1}$.

For transverse coherence subject to free precession under the Zeeman Hamiltonian, the evolution of the magnetization is described by the modified Bloch or McConnell equations:⁶¹

$$\begin{aligned} \frac{d}{dt} \begin{bmatrix} M_A^+(t) \\ M_B^+(t) \end{bmatrix} &= \begin{bmatrix} -i\Omega_A - R_{2A}^0 - p_B k_{ex} & p_A k_{ex} \\ p_B k_{ex} & -i\Omega_B - R_{2B}^0 - p_A k_{ex} \end{bmatrix} \\ &\times \begin{bmatrix} M_A^+(t) \\ M_B^+(t) \end{bmatrix} \end{aligned} \quad (13)$$

The solution of these equations is:

$$\begin{bmatrix} M_A^+(t) \\ M_B^+(t) \end{bmatrix} = \begin{bmatrix} a_{AA}(t) & a_{AB}(t) \\ a_{BA}(t) & a_{BB}(t) \end{bmatrix} \begin{bmatrix} M_A^+(0) \\ M_B^+(0) \end{bmatrix} \quad (14)$$

in which $M_A^+(t) = M_{Ax}(t) + iM_{Ay}(t)$, $M_B^+(t) = M_{Bx}(t) + iM_{By}(t)$,

$$\begin{aligned} a_{AA}(t) &= \frac{1}{2}[(1 - \Lambda) \exp(-\lambda_- t) + (1 + \Lambda) \exp(-\lambda_+ t)] \\ a_{BB}(t) &= \frac{1}{2}[(1 + \Lambda) \exp(-\lambda_- t) + (1 - \Lambda) \exp(-\lambda_+ t)] \\ a_{AB}(t) &= \frac{k_{ex} p_A}{\lambda_+ - \lambda_-}[(\exp(-\lambda_- t) - \exp(-\lambda_+ t))] \\ a_{BA}(t) &= \frac{k_{ex} p_B}{\lambda_+ - \lambda_-}[(\exp(-\lambda_- t) - \exp(-\lambda_+ t))] \end{aligned} \quad (15)$$

and,

$$\Lambda = \frac{-i\Delta\omega + R_{2A}^0 - R_{2B}^0 + k_{ex}(p_B - p_A)}{\lambda_+ - \lambda_-}$$

$$\lambda_{\pm} = \frac{1}{2}\{-i\Omega_A - i\Omega_B + R_{2A}^0 + R_{2B}^0 + k_{ex} \pm [(-i\Delta\omega + R_{2A}^0 - R_{2B}^0 + k_{ex}(p_B - p_A))^2 + 4p_A p_B k_{ex}^2]^{1/2}\}$$
(16)

The NMR spectrum is given by the Fourier transformation of $M_A^+(t) + M_B^+(t)$. Computer optimization of the parameters in equations (14)–(16) is utilized to fit the experimental lineshapes. In practical applications, particularly for ^1H lineshapes, the magnetization components in equations (14)–(16) should

Figure 4 Lineshape analysis for folding of λ repressor. The aromatic regions of the ^1H NMR spectra of the monomeric Gly 46 Ala/Gly 48 Ala mutant of λ repressor (residues 6–85) at 30 °C are shown for urea denaturant concentrations of (a) 0 M, (b) 2.2 M, (c) 4.1 M, (d) 5.1 M, (e) 7.0 M, and (f) 8.9 M. Expansions of the (g) experimental and (h) fitted ^1H aromatic spectra also are shown for λ repressor in 4.1 M urea. (Reproduced with permission from *J. Biomol. NMR*, 1998, **11**, 355–359)

be regarded as representing individual resonance lines of scalar coupled multiplets. If scalar coupling constants are modulated by the exchange process, then the more general theoretical approach described in **Chemical Exchange Effects on Spectra**, Volume 2 is required.

Folding of the Gly 46 Ala/Gly 48 Ala mutant of monomeric λ repressor has been investigated as a function of urea denaturant concentration by Oas and coworkers using ^1H one-dimensional spectroscopy.⁶² The aromatic regions of a series of NMR spectra are shown in Figure 4 to illustrate the changes in lineshape observed as the urea concentration is increased from 0 to 8.9 M. Figure 4(h) and (g) compare the experimental and fitted lineshapes for a single urea concentration of 4.1 M. Data were analyzed using the program ALASKA to fit k_1 (unfolding) and k_{-1} (folding) assuming values of other spectral parameters for folded and unfolded species obtained from the spectra recorded at 0 and 8.9 M urea, respectively.⁶² In most cases, lineshape analyses have been restricted to one-dimensional ^1H spectra; however, two-dimensional lineshape analysis using X– ^1H heteronuclear correlation spectroscopy yields increased spectral resolution, provides lineshape information for both the ^1H and X spins, and exhibits simplified lineshapes in indirect frequency dimensions because heteronuclear scalar coupling interactions are easily decoupled. As an example, ^{15}N – ^1H HSQC spectroscopy has been used in a lineshape analysis of the dimerization of the protein barstar.¹³

6 $R_{1\rho}$ ROTATING FRAME RELAXATION METHODS

In an $R_{1\rho}$ experiment, magnetization is spin-locked in the rotating frame by application of a radio-frequency field.^{27,28} The relaxation rate constant for the component of the magnetization along the direction of effective field in the rotating frame is called $R_{1\rho}$ and depends on the amplitude, ω_1 , and frequency, ω_{rf} , of the applied radiofrequency field. The effective field in the rotating frame is $\omega_e = (\Omega^2 + \omega_1^2)^{1/2}$ in which $\Omega = p_A\Omega_A + p_B\Omega_B$ is the population-average chemical shift, and the tilt angle of the effective field is given by $\tan \theta = \omega_1/\Omega$. $R_{1\rho}$ experiments are sensitive to chemical exchange processes if values of ω_e near k_{ex} are achievable experimentally. Typically, $R_{1\rho}$ experiments are limited to values of $k_{ex} < 10^5 \text{ s}^{-1}$. Sample heating and limitations on the maximum value of ω_1 tolerated by the spectrometer probe and amplifiers during sustained spin-locking pulses are the principal experimental constraints on ω_e . Furthermore, exchange processes with $k_{ex} > 10^5 \text{ s}^{-1}$ result in small exchange linebroadening unless $\Delta\omega$ is very large. $R_{1\rho}$ measurements on biological macromolecules can be performed using near-resonance (often called on-resonance for convenience)⁶⁵ or off-resonance^{66–68} rf fields. In the former case, the rf transmitter frequency is positioned close to the resonances of interest (or in the middle of the NMR spectrum) and the minimum value of ω_1 is large enough to ensure that $\theta > 70^\circ$ over the spectral region of interest. The relaxation dispersion curve is obtained by varying ω_1 . In the latter case, the rf transmitter is positioned far enough off-resonance to ensure that $\theta < 70^\circ$. The relaxation dispersion curve is obtained by varying ω_1 or the carrier offset or both in order to vary ω_e .

A pulse sequence for an off-resonance $R_{1\rho}$ experiment for X spins is shown in Figure 5(a)^{66–68} and a pulse sequence

Figure 5 Pulse sequences for (a) X-nucleus and (b) ^1H -nucleus $R_{1\rho}$ experiments.^{65–68,71} Narrow and wide bars depict 90° and 180° pulses respectively. All pulses are x-phase unless otherwise indicated. Decoupling during acquisition is achieved with the GARP sequence.⁹² The unlabeled gradients are used to suppress unwanted coherences and pulse imperfections.⁹³ Delays are $\Delta = 1/(4J_{XH})$, $t_1^a = \Delta + t_1/2$, t is the relaxation delay, and δ is longer than the duration of the gradients applied during δ . (a) The spin-lock rf frequency is set outside the spectral region of interest. The adiabatic sweep A rotates z-magnetization to the direction of the effective field and the adiabatic sweep B rotates the spin-locked magnetization back to the z-axis.^{66,68} The phase cycle is $\phi_1 = x, -x$; $\phi_2 = 4(x), 4(-x)$; $\phi_3 = x, x, y, y, -x, -x, -y, -y$; $\phi_4 = x$; receiver = $x, -x, -x, x$. Gradient coherence selection are achieved with gradients Gd and Ge. Echo/antiecho signals are recorded in separate experiments by inverting the amplitude of Gd and phase ϕ_4 .⁹⁵ The ϕ_1 and the receiver phases are inverted for each t_1 increment to shift axial peaks to the edge of the spectrum.⁹⁴ (b) The spin-lock rf frequency is positioned in the center of the spectral region of interest, and $\chi = 1/(2\omega_1)$ serves to align the magnetization along the direction of the effective field.⁹⁶ The phase cycle is $\phi_1 = x, -x$; $\phi_2 = 4(x), 4(-x)$; $\phi_3 = x, x, -x, -x$; and receiver = $x, -x$. Frequency discrimination is obtained by shifting the phase of the receiver and ϕ_1 according to the States-TTPI protocol⁹⁴

for a near-resonance $R_{1\rho}$ experiment for ^1H spins is shown in Figure 5(b).^{69,70} The pulse sequence in Figure 5(b) is applicable to ^1H spins that do not have significant homonuclear scalar coupling interactions; for example, the $^3J_{\text{N}\alpha}$ scalar coupling interaction is eliminated in uniformly $^{15}\text{N}/^2\text{H}$ enriched proteins.⁷¹

$R_{1\rho}$ experiments have been applied principally to characterize kinetic processes in the fast-exchange limit ($k_{\text{ex}}/\Delta\omega \gg 1$) using the theoretical expression:^{27,28,72}

$$R_{1\rho}(\omega_e) = R_2^0 \sin^2 \theta + R_1 \cos^2 \theta + \sin^2 \theta \frac{\Phi_{\text{ex}} k_{\text{ex}}}{k_{\text{ex}}^2 + \omega_e^2} \quad (17)$$

in which R_2^0 and R_1 are population-averaged relaxation rate constants and $\Phi_{\text{ex}} = p_A p_B \Delta\omega^2$. Other expressions applicable

outside of the fast-exchange limit have been derived, but have not been applied yet to relaxation in proteins.^{72,73} The dependence of $R_{1\rho}$ on R_1 in equation (17) can be removed either by the constant-relaxation time approach⁶⁷ or by independently measuring R_1 . The number of independent parameters in equation (17) can be further reduced either by measuring R_2^* ³⁵ or R_2^0 .⁷

The folding equilibrium of the peripheral subunit binding domain (PSBD) from the dihydrolopoamide acetyltransferase component of the pyruvate dehydrogenase multienzyme complex from *Bacillus stearothermophilus* has been characterized using ^{15}N $R_{1\rho}$ measurements.⁷ R_1 was measured independently and R_2^0 was obtained from measurements of η_{xy} using equation (8) in order to express R_{ex} as

$$R_{\text{ex}} = \frac{R_{1\rho}}{\sin^2 \theta} - \frac{R_1}{\tan^2 \theta} - R_2^0 = \frac{\Phi_{\text{ex}} k_{\text{ex}}}{k_{\text{ex}}^2 + \omega_e^2} \quad (18)$$

The relaxation dispersion curve is linearized by plotting $1/R_{\text{ex}}$ versus ω_e^2 , as shown in Figure 6(a). Values of $k_{\text{ex}} = (b/m)^{1/2}$ and $\Phi_{\text{ex}} = (mb)^{-1/2}$ are obtained from the slope m and intercept b .⁷⁴ In the fast-exchange limit, p_A , p_B , and $\Delta\omega$ cannot be obtained separately from Φ_{ex} by fitting the relaxation dispersion. However, Φ_{ex} and Ω are related by $\Phi_{\text{ex}} = -\Omega^2 + a\Omega - b$ in which $a = \Omega_A + \Omega_B$ and $b = \Omega_A \Omega_B$. If Φ_{ex} and Ω are measured as a function of temperature

Figure 6 ^{15}N $R_{1\rho}$ relaxation dispersion for Ala 11 of PSBD. (a) Data recorded at 304 (O), 313 (▲), and 323 K (▼).⁷ R_{ex} data for Ala 11 were obtained from equation (18), values of R_1 and η_{xy} were measured by conventional approaches,^{29,44} and values of R_2^0 obtained from η_{xy} using equation (8). The best least squares fitted line is drawn for each data set. (b) Φ_{ex} is plotted versus the isotropic shift Ω at each temperature. The solid line is the best fit to determine the x-intercepts $\Omega_A = 118.80 \pm 0.02$ ppm and $\Omega_B = 126.7 \pm 0.4$ ppm with $\Delta\omega = 7.9 \pm 0.4$ ppm. (c) Arrhenius plot for (O) folding (k_{-1}) and (●) unfolding (k_1) rate constants. The apparent activation barriers are 17 ± 14 kJ mol $^{-1}$ for folding and 125 ± 19 kJ mol $^{-1}$ for unfolding

and Ω_A and Ω_B are assumed to be independent of temperature, then the coefficients a and b can be determined by least squares optimization. Subsequently, $|\Delta\omega| = (a^2 - 4b)^{1/2}$, and $\Omega_{A,B} = [a \pm (a^2 - 4b)^{1/2}]/2$. Once $\Delta\omega$ is known, p_A , p_B , k_1 , and k_{-1} are obtained from Φ_{ex} and k_{ex} at each temperature. An example of this analysis is shown in Figure 6(b); the temperature dependence of the rate constants obtained from this analysis is shown in Figure 6(c). The chemical shift of the (unobserved) unfolded PSBD species is determined to be 126.7 ± 0.4 ppm; this value is in good agreement with the predicted random coil chemical shift of 126.0 ppm for an Ala residue preceded by a Tyr residue.⁷⁵

7 CPMG RELAXATION METHODS

In a CPMG experiment, the relaxation of transverse magnetization is observed during a $(\tau - 180^\circ - 2\tau - 180^\circ - \tau)_n$ spin-echo sequence, in which $\tau_{cp} = 2\tau$ is the spacing between 180° pulses and n is an integer.^{25,26} CPMG experiments are sensitive to chemical exchange processes if values of $1/\tau_{cp}$ near k_{ex} are achievable experimentally. CPMG experiments in proteins typically are applicable to chemical exchange processes with values of $k_{ex} < 10^4 \text{ s}^{-1}$ as a result of experimental constraints on the minimum value of τ_{cp} . Sample heating at high pulsing rates is a major experimental limitation. In addition, theoretical analyses of relaxation during CPMG experiments assume that the refocusing pulses have negligible duration;^{76–78} at pulse duty cycles $> 10\%$, this assumption may not be valid.⁶⁶ The maximum value of τ_{cp} for CPMG experiments applied to X spins is limited by evolution under the one-bond heteronuclear scalar coupling Hamiltonian, which interconverts in-phase and antiphase magnetization during the spin-echo period. The relaxation rate constant for heteronuclear antiphase magnetization includes a contribution from longitudinal relaxation of the coupled ^1H spin and is greater than the rate constant for in-phase magnetization. To minimize contributions from antiphase magnetization, $\tau_{cp} < 1/(4J_{XH})$, where J_{XH} is the one-bond heteronuclear scalar coupling constant; therefore, the maximum values of τ_{cp} are 1.7 ms for ^{13}C and 2.6 ms for ^{15}N .

The range of τ_{cp} values that can be utilized is expanded by CPMG experiments designed to average in-phase and antiphase magnetization. Relaxation-compensated CPMG pulse sequences for IS,⁷⁹ I₂S,⁸⁰ and I₃S⁸¹ are shown in Figure 7. In these experiments, in-phase and antiphase coherences are interchanged during the period U in order to eliminate any τ_{cp} -dependent effects arising from differential relaxation rates. Conventional CPMG pulse sequences for measuring R_2 are self-compensating for evolution of the scalar coupling if $\tau_{cp} = m/J_{XH}$, in which m is an integer.⁴⁸ Hahn spin echo measurements, self-compensated CPMG experiments and relaxation-compensated CPMG experiments can be used in combination to cover the widest possible range of τ_{cp} values.⁴⁸ For I₂S and I₃S spin systems, relaxation is multiexponential and constant relaxation time experiments are necessary to obtain accurate results.^{80,81}

These approaches are illustrated in Figure 8 for residue Cys 38 in BPTI at temperatures of 300 and 313 K.⁴⁸ The backbone ^{15}N resonance of Cys 38 is broadened as a result of isomerization of the Cys 14–Cys 38 disulfide bond. The

Figure 7 Pulse sequences for relaxation-compensated CPMG experiments in (a) IS, (b) I₂S, and (c) I₃S spin systems.^{48,79} Narrow and wide bars depict 90° and 180° pulses respectively. All pulses are x-phase unless otherwise indicated. Decoupling during acquisition is achieved with the GARP or WALTZ-16 sequences.^{53,92} Delays are $\tau = \tau_{cp}/2$, $\Delta = 1/(4J_{XH})$, and $\delta > \text{Gd}$. In (a) $t_1^a = \Delta + t_1/2$; in (b) $\varepsilon = 1/(8J_{XH})$, $t_1^a = \zeta + t_1/2$, and $\zeta > \text{Ge}$; and in (c) $\zeta = 1/(10J_{XH})$. In (a) and (b), the phase cycle is $\phi_1 = x, -x$; $\phi_2 = 4(x), 4(-x)$; $\phi_3 = x, x, y, y, -x, -x, -y, -y$; $\phi_4 = x$; receiver = $x, -x, -x, x$. The unlabeled gradients are used to suppress unwanted coherences and pulse imperfections.⁹³ Gradient coherence selection are achieved with gradients Gd and Ge. Echo/antiecho signals are recorded in separate experiments by inverting the amplitude of Gd and phase ϕ_4 .⁹⁵ The ϕ_1 and the receiver phases are inverted for each t_1 increment to shift axial peaks to the edge of the spectrum.⁹⁴ In (c), the phase cycle is $\phi_1 = x, -x$; $\phi_2 = 2(x), 2(-x)$; $\phi_3 = 8(x), 8(-x)$; $\phi_4 = 4(x), 4(y), 4(-x), 4(-y)$; receiver = $x, -x, -x, x, -x, x, x, -x$. The unlabeled gradients are used to suppress unwanted coherences and pulse imperfections.⁹³ Frequency discrimination during t_1 is obtained by shifting the phase of ϕ_2 and the receiver according to the States-TTPI protocol⁹⁴

values of $R_2(1/\tau_{cp})$ were acquired using the pulse sequence of Figure 7(a) for values of $\tau_{cp} < 10$ ms, a self-compensated pulse sequence for $\tau_{cp} = 10.8$ and 21.5 ms, and a Hahn-echo

Figure 8 Global analysis of chemical exchange for the ^{15}N spin of Cys 38 in BPTI. Values of $R_2(1/\tau_{cp})$ at (●) $B_0 = 11.7$ T and (○) $B_0 = 14.1$ T are shown at temperatures of (a) 300 K and (b) 313 K. At 300 K, fitting with equation (19) yields $p_A = 0.953 \pm 0.004$, $\Delta\omega = 8.9 \pm 0.4$ ppm, $k_{ex} = 380 \pm 70$ s $^{-1}$ and $R_2^0 = 8.6 \pm 0.1$ s $^{-1}$. At 313 K, fitting with equation (21) yields $\Phi_{ex} = 0.108 \pm 0.024$ ppm 2 , $k_{ex} = 1300 \pm 290$ s $^{-1}$, and $R_2^0 = 6.4 \pm 0.7$ s $^{-1}$

pulse sequence for $\tau_{cp} = 64.5$ ms.⁴⁸ Dispersion data were fit with a general expression for the transverse relaxation rate constant for site A ($p_A > p_B$), $R_2(1/\tau_{cp})$ given by,^{28,77,82}

$$R_2\left(\frac{1}{\tau_{cp}}\right) = R_2^0 + \frac{k_{ex}}{2} - \frac{1}{2\tau_{cp}} \cosh^{-1} [D_+ \cosh(\eta_+) - D_- \cos(\eta_-)] \quad (19)$$

in which,

$$D_{\pm} = \frac{1}{2} \left[\pm 1 + \frac{\Psi + 2\Delta\omega^2}{(\Psi^2 + \zeta^2)^{1/2}} \right] \quad (20)$$

$$\eta_{\pm} = \frac{\tau_{cp}}{\sqrt{2}} \left[\pm \Psi + (\Psi^2 + \zeta^2)^{1/2} \right]^{1/2}$$

$\Psi = k_{ex}^2 - \Delta\omega^2$ and $\zeta = 2\Delta\omega k_{ex}(p_B - p_A)$ and identical relaxation rates R_2^0 have been assumed for the two sites. In the fast-exchange limit, equation (19) is approximated by,⁸³

$$R_2\left(\frac{1}{\tau_{cp}}\right) = R_2\left(\frac{1}{\tau_{cp}} \rightarrow \infty\right) + \frac{\Phi_{ex}}{k_{ex}} \left[1 - \frac{2}{k_{ex}\tau_{cp}} \tanh\left(\frac{k_{ex}\tau_{cp}}{2}\right) \right] \quad (21)$$

and R_2^0 is the population-average value. The static magnetic field dependence of exchange linebroadening indicates that the exchange time scale is intermediate at 300 K and approaches the fast limit at 313 K. Consequently, dispersion curves recorded at two static magnetic field strengths were analyzed globally using equations (19) for data acquired at 300 K and equation (21) for data acquired at 313 K. Analysis of data recorded at a single static magnetic field or data recorded for a limited range of τ_{cp} values can give substantial systematic errors.^{48,79} Simultaneous analysis of both CPMG and $R_{1\rho}$ data has been proposed to increase the range of accessible effective fields and robustness of the data analysis.^{5,10}

The pulse sequences shown in Figure 7 average the relaxation rate constants for in-phase and antiphase magnetization; consequently, R_2^0 in these sequences is larger than the in-phase relaxation rate constant and contains contributions from ^1H longitudinal relaxation. For IS spin systems, relaxation periods for two-spin order can be incorporated into the pulse sequence of Figure 5(a) to remove the contributions to $R_2(1/\tau_{cp})$ from ^1H longitudinal relaxation.⁸⁴ For ^{15}N spins, this method facilitates the use of relaxation interference rate constants to determine R_2^0 [equations (7) and (8)] and enables faster kinetic processes to be investigated by CPMG methods. Wüthrich and coworkers have shown that significantly narrower NMR signals can be obtained for one component of the ^{15}N - ^1H scalar-coupled doublet from cancellation of ^1H - ^{15}N dipole-dipole and ^{15}N CSA interactions (see **Transverse Relaxation-optimized NMR Spectroscopy with Biomacromolecular Structures in Solution**).⁸⁵ Recently, CPMG pulse sequences have been modified to select the narrow TROSY doublet component during the relaxation period, the indirect labeling period, and the detection period.^{71,86,87} These modifications facilitate the quantification of exchange linebroadening contributions in larger macromolecules because the relative conformational exchange contribution to the phenomenological relaxation rate constant during the CPMG period is enhanced and the improved resolution and sensitivity of TROSY ^1H - ^{15}N correlation spectra are obtained.

8 CHEMICAL EXCHANGE IN MULTIPLE QUANTUM SPECTROSCOPY

If two spins are affected by the same chemical exchange kinetic process, then the chemical shift changes for the two spins resulting from transitions between sites will be correlated. This correlation gives rise to exchange effects that can either broaden or narrow resonance lineshapes for multiple quantum coherences.⁸⁸ In essence, for multiple quantum coherences, the value of $\Delta\omega$ in the equations given above should be replaced by the difference in multiple quantum frequencies, $\Delta\omega_{MQ}$; thus, for double (DQ) and zero (ZQ) quantum coherences, respectively, $\Delta\omega_{DQ} = \Delta\omega_I + \Delta\omega_S$ and $\Delta\omega_{ZQ} = \Delta\omega_I - \Delta\omega_S$, in which $\Delta\omega_I$ ($\Delta\omega_S$) is the chemical shift difference between sites A and B for the I (S) spin. Hahn spin-echo pulse sequences for measuring the difference between the relaxation rate constants for DQ and ZQ quantum coherences have been developed for ^1H - ^{15}N backbone amide moieties⁸⁹ and for $^{13}\text{C}^\alpha$ - $^{13}\text{C}^\beta$ moieties⁹⁰ in proteins. The sign of the difference between DQ and ZQ relaxation rate constants gives the relative sign of the chemical shift differences for ^1H and ^{15}N spins. This information, which cannot be obtained

from single quantum experiments, is helpful for mechanistic interpretations of exchange phenomena. In some cases, selection of the narrower of the DQ or ZQ coherences (depending on the relative chemical shifts) results in improved resolution and sensitivity of multidimensional NMR spectra.^{88,91}

9 CONCLUSIONS

Chemical exchange effects in NMR spectroscopy provide information on conformational and chemical kinetic processes occurring in biological macromolecules on biologically-relevant time scales. Experimental methods described in this article enable chemical exchange constants, k_{ex} , to be determined over a range from 0.1 to 10^5 s^{-1} using ZZ-exchange, lineshape, CPMG, and $R_{1\rho}$ methods. Applications of these techniques promise to enhance understanding of the biological function of kinetic processes on μs -s time scales in proteins and other biological macromolecules.

1 INTRODUCTION

The study of tertiary and quaternary structures, binding and aggregation is of central importance in the biological, chemical and pharmaceutical sciences. For example, the homo- and hetero-associations of proteins are important in normal physiological conditions, some diseases (e.g., Alzheimer's disease), protein pharmaceutical development and crystallization. Due to its non-invasive nature and that it provides an estimate of the self-diffusion coefficient, as opposed to the mutual diffusion coefficient, pulsed-gradient spin-echo (PGSE) NMR translational diffusion measurements (also commonly referred to as DOSY or PFG NMR) provide an ideal way for studying what are generally such weakly interacting systems. Such measurements provide complementary information to traditional NMR structural studies and can provide information on conformation even when individual assignments of the resonances of a macromolecule are unknown. The basis of using diffusion measurements to probe such systems relies on the different species being able to be separated by differences in their diffusion coefficients and additionally, in the case of binding studies, the exchange between the free and bound states modulates the observed diffusion coefficient. Although the application of PGSE diffusion measurements to study conformation, binding and aggregation has a long history, it has undergone a tremendous resurgence in the last decade due to both the commercial availability of the requisite hardware for performing such measurements and also due to the realization of its applicability to a wide variety of applications.

This chapter is concerned with the applications of PGSE diffusion measurements to study conformation, binding and

association. In Section 2, a few salient remarks on translational diffusion are given. In Section 3, exchange and binding are considered. Some of the recent applications are reviewed in Section 4, and finally, in Section 5 some of the practical aspects of PGSE diffusion measurements are presented. Special attention is given to developments since the publication of the main volumes of the Encyclopedia. Due to space limitations, generally only recent references, from which the history can be traced, are given. Studies involving polymers, liquid crystals, porous systems, restricted diffusion and imaging are outside the scope of the present chapter.

2 TRANSLATIONAL DIFFUSION AND SOLUTE CONCENTRATION

2.1 Diffusion at Infinite Dilution

At infinite dilution, the translational diffusion coefficient, D^0 , of a solute species is often related to its friction coefficient, f , and to the solvent viscosity, η , by the Stokes–Einstein equation, which is derived assuming that the solute sees the solvent as a continuum (e.g., see Ref.¹),

$$D^0 = \frac{kT}{f} \quad (1)$$

where k is the Boltzmann constant and T is the temperature. For the particularly simple case of a sphere under stick boundary conditions, f is given by (Stokes law)

$$f = 6\pi\eta R \quad (2)$$

where R is the effective hydrodynamic (or Stokes) radius. Exact solutions are only known for some simple geometries (e.g., see Table 1 in Ref.²). However, since f is determined by the overall dimensions of the diffusing species (which may include the effects of solvation and rugosity), few species are well described by a simple geometry. Consequently, f must normally be determined numerically (e.g., Ref.³).

The difficulty in modeling the hydrodynamics is greatly increased in associating systems. If the monomer–monomer contact in oligomeric species can be regarded as hard-sphere contact, the ratio of the diffusion coefficient at infinite dilution of an n -mer, D_n^0 , to that of the monomer can be modeled as

$$\frac{D_n^0}{D_1^0} = \frac{f_1}{f_n} = F_n n^{-1/3} \quad (3)$$

and the values of F_n for various geometries have been determined.⁴ Generally, there is but no recourse but to consider all oligomers as hydrodynamically spherical, thus, the friction coefficient increases according to the inverse cube root of the molecular weight. In defense of this simplistic assumption, the friction coefficients calculated from equation (3) for reasonable geometrical possibilities for the oligomeric shapes are all quite close to that obtained for a sphere of equivalent volume.

2.2 Diffusion at Finite Concentrations

Aggregating systems are often ‘crowded’ in that the average spacing between the solute molecules is much less than the

mean-squared displacement of the particles over the timescale of the PGSE diffusion experiment (i.e., Δ ; vide infra). At finite solute concentrations, the diffusion coefficients of both the solute and the solvent will be affected due to the solute molecules lengthening the diffusion path of the solvent (i.e., ‘obstruction’), and similarly, the solute molecules effecting the diffusion path of themselves (i.e., ‘self-obstruction’ or ‘crowding’). Obstruction can be visualized as restriction by a complicated, and perhaps time-dependent geometry, and it has the effect of reducing the diffusion coefficient of both the solvent and solute. Since the degree of obstruction is dependent on the shapes of the obstructing particles, it provides an additional source of structural information. Calculation of the diffusion reduction factor, f_C , is exceedingly difficult and exact solutions are known only for some very simple cases, and in general, analysis is performed using various approximations or numerical simulations (see Figure 1).^{5–8} The currently available models contain serious limitations, not the least being that they do not account for the presence

of an aggregation process. Consequently, f_C is progressively overestimated as the concentration (and thus often the degree of aggregation) increases.

3 ANALYSIS OF PGSE DIFFUSION DATA

3.1 PGSE Data from Multicomponent Systems

The basics of the PGSE measurements have been considered previously in this encyclopedia and elsewhere.^{9,10} A further and rather obvious complication in modeling of the diffusive behavior of interacting systems is the lifetime of the individual species and this is likely to be very sample specific. In the case of aggregating protein species, the lifetime is often found to be long on the timescale of the PGSE experiment, Δ (typically tens to hundreds of milliseconds), whereas for ligand–protein interactions it is generally short.

It is commonly found that the resonances of the different species overlap, and thus, the PGSE attenuation data is the sum of all of the intensities from each of the species multiplied by their respective relaxation time(s). If the exchange between these species is slow (with respect to Δ), then the echo signal amplitude from a Hahn-echo based sequence for n different oligomeric species present (e.g., monomer, dimer... n -mer) undergoing isotropic free diffusion is given by (in the short gradient pulse limit)

$$S(g) = \sum_n M_{0,n} \exp(-\gamma^2 g^2 \delta^2 \Delta D_n) \exp\left(\frac{-2\tau}{T_{2,n}}\right) \quad (4)$$

where $M_{0,n}$ denotes the equilibrium magnetization ($\propto Mw_n n_n$; where Mw_n is the molar mass of the n th aggregate species and n_n is the number of such molecules present), $T_{2,n}$ is the spin–spin relaxation time of the n th resonance, 2τ is the total echo time, γ is the gyromagnetic ratio, g is the magnitude and δ is the duration of the magnetic field gradient pulses and Δ is the separation between the leading edges of the gradient pulses. Modeling of the populations of the different oligomeric species is considered in Section 3.2. For a stimulated echo (STE) based sequence, relaxation weighting due to spin–lattice relaxation would also be included. Neglecting the relaxation effects, the PGSE NMR data can then be normalized,

$$E(q, \Delta) = \frac{S(q, 2\tau)}{S(0, 2\tau)} = \frac{\sum_n Mw_n n_n \exp(-4\pi^2 q^2 \Delta D_n)}{\sum_n Mw_n n_n} \quad (5)$$

and for brevity, we have set $q = (2\pi)^{-1} \gamma g \delta (m^{-1})$. If the exchange is fast (with respect to Δ) then equation (5) reduces to a single exponential,

$$E(q, \Delta) = \exp(-4\pi^2 q^2 \Delta \langle D \rangle_w) \quad (6)$$

where $\langle D \rangle_w$ is the mass averaged diffusion coefficient defined by

$$\langle D \rangle_w = \frac{\sum_n Mw_n n_n D_n}{\sum_n Mw_n n_n} \quad (7)$$

Figure 1 Off-lattice random flight simulations of (a) the isotropically averaged obstruction factor ($=f_C$) and (b) obstruction anisotropy [$=(f_{C\parallel} - f_{C\perp})/\langle f_C \rangle$] versus the aspect ratio of spheroids (●), disks (○) and spherocylinders (◐) on an expanded face centered cubic lattice at a volume fraction of 0.3. The effective cell approximation result is also given (dashed curves). (Reproduced by permission of the American Institute of Physics from H. Jóhannesson and B. Halle, *J. Chem. Phys.*, 1996, **104**, 6807)

For example, in the case of a two-site system, such as a ligand (e.g., a peptide) in fast exchange (with respect to Δ) between free and bound (e.g., bound to a micelle) forms with diffusion coefficients D_f and D_b , respectively, the echo attenuation would appear to be single exponential (i.e., equation (6)) with an apparent diffusion coefficient being given by

$$\langle D \rangle_w = P_b D_b + P_f D_f \quad (8)$$

where P_b and $P_f (=1 - P_b)$ are the populations of the bound and free forms. Hence, information on the binding isotherm can be obtained by performing experiments with different relative concentrations of the ligand to the macromolecule. If the exchange is intermediate on the timescale, the attenuation function is more complicated.^{11,12} Binding studies are considered in greater detail in Section 3.3.

For only small degrees of polydispersity, the multi-exponential nature of the attenuation (i.e., equation (5)) is not apparent – especially if a microscopic averaging process exists such that the range of diffusion coefficients measured are narrower than would have been expected on the basis of the polydispersity.¹³ Thus, with the exception of highly polydisperse polymer systems, only a single ‘average’ diffusion coefficient is normally obtained from the PGSE data.^{14,15} The averaging process can be approximated by taking the cumulant expansion of equation (5) (to second order),

$$\ln(E(q, \Delta)) = -4\pi^2 q^2 \Delta \langle D \rangle_w + \frac{(4\pi^2 q^2 \Delta)^2}{2} (\langle D^2 \rangle_w - \langle D \rangle_w^2) \quad (9)$$

The second term in equation (9) (i.e., the ‘variance’) reflects the degree of polydispersity and may become evident as non-linearity in the attenuation plot (i.e., $\ln(E)$ vs. q^2) at larger q values. Ideally, PGSE data from a sample containing a number of species can be decomposed to obtain the individual diffusion coefficients of the species. However, the decomposition of such multi-exponential data is fraught with difficulty¹⁶ and meaningful attempts require prior knowledge such as the number of components.¹⁷ Results of such attempts to spectrally separate the components of a mixture on the basis of their diffusion coefficient are often displayed in a two-dimensional format generally referred to as DOSY.^{18,19} However, the crowding effects that occur at finite concentrations mediate against the success of such multi-exponential decompositions.

When the measured attenuation plots appear linear, analysis proceeds by fitting equation (9) (excluding the second term) to the attenuation data. Since the diffusion coefficients of the oligomers (i.e., D_i) inherently contain the effects of crowding, analysis of the results of the PGSE experiment yields the apparent diffusion coefficient, $\langle D \rangle_w^C$, where the superscript C denotes the inclusion of crowding effects. Interestingly, equation (9) is, due to the effects of the microscopic averaging, mathematically equivalent to that for the case of fast exchange (equation (6)).

3.2 Models for Self-Associating Systems

Given the realistic limits of the sort of aggregate distributions/models that can feasibly be tested against the experimental PGSE NMR data and the effects of crowding, a practical

Figure 2 A schematic diagram of the steps involved in analyzing the PGSE data of an aggregating protein system. (Reproduced by permission of the American Chemical Society from W. S. Price, F. Tsuchiya, and Y. Arata, *J. Am. Chem. Soc.*, 1999, **121**, 11 503)

approach to evaluating PGSE diffusion data for an aggregating protein system is outlined in Figure 2. Typically the exact populations of the n -mers are not known and instead equation (4) is expressed in terms of a discrete or continuous distribution.^{15,20} For example, in the isodesmic model, aggregates grow by the addition of a monomer unit, L_1 , thus,

where $K_e (= K_2 = K_3 = \dots = K_n)$ is the equilibrium constant. From the conservation of mass equation, we have

$$C = \sum_{n=1}^{\infty} c_n n \quad (11)$$

Thus the mole fraction of the n -mer is given by

$$\alpha_n = n(K_e C)^{n-1} \left(\frac{2K_e C + 1 - \sqrt{1 + 4K_e C}}{2(K_e C)^2} \right)^n \quad (12)$$

Hence, the theoretical apparent diffusion coefficient for a polydisperse oligomeric system is given by (NB $Mw_n n_n \propto c_n n$)

$$\begin{aligned} \langle D \rangle_w^C &= \langle D \rangle_w f_C(C) = \frac{\sum_n c_n n D_1^0 n^{-\frac{1}{3}}}{C} f_C(C) \\ &= \sum_n \alpha_n D_1^0 n^{-\frac{1}{3}} f_C(C) \end{aligned} \quad (13)$$

3.3 Binding Studies

Binding studies can proceed in a number of ways depending upon the sample experimental conditions: (1) If (some of) the ligand resonances are distinct from those of the protein, the ligand diffusion coefficient can be measured directly, (2) if the resonances are overlapped, it may be possible to separate the attenuation curves if the exchange rate is slow (with respect to Δ), (3) edit out signals from one of the species by applying relaxation or diffusion filters or (4) to use specific isotopic labeling in conjunction with heteronuclear filtration.^{21,22}

4 APPLICATIONS

A number of reviews are either entirely devoted to or contain some coverage of diffusion-based studies of association, binding and conformation.^{12,19,22–29} Some of the more interesting studies from the literature are cited in the following, somewhat loosely classified, sub-sections.

4.1 Conformation

PGSE measurements have shown that the *cis*- and *trans*-conformers of *N*-methylformamide have different diffusion

coefficients.³⁰ On a more macroscopic scale PGSE was used to probe the conformation of amylopectin³¹ and to determine the radii of dendrimers.³²

In a pioneering study in 1968, the helix to random coil transition of poly-L-glutamic acid as a function of pH was studied using PGSE NMR.³³ Recent studies have included BPTI and unfolded variants,³⁴ urea-induced unfolding of lysozyme³⁵ and the effects of pH and NaCl concentration on the heterodimeric salt-mediated killer toxin (SMKT) from *Pichia farinosa*.³⁶ Both the lysozyme and SMKT studies revealed that as a protein loses its compact structure and becomes a random coil, there is a $\sim 37\%$ increase in effective hydrodynamic radius. PGSE measurements have even been used to study the folding process of lactalbumin in real time.³⁷

Some examples of protein diffusion coefficients are given in Table 1, and also in Table 4 in Ref.²⁷. Since equation (1) only rigorously applies at infinite dilution, to extract conformational information, it is generally necessary to extrapolate the results of diffusion measurements to infinite dilution (e.g., see Ref.³⁴). Further, changes in solvent viscosity must be accounted for to avoid misinterpretation.³⁶ Experimentally, it has been found that the self-diffusion coefficients of the proteins correlate

Table 1 Selected diffusion coefficients of biological molecules derived from PGSE NMR measurements^{a,b}

Protein/solute	Concentration; pH (or pD)	Solvent	<i>T</i> (K)	<i>D</i> (m ² s ^{−1})	Reference
BPTI	7.5 mg/ml	CO ₂ /TFE/detergent	293	2.5×10^{-9}	102
BPTI	Infinite dilution ^c 4.5	D ₂ O	274	7.7×10^{-10}	34
Calbindin-D _{9k}	1–2 mM	90% H ₂ O		1.11×10^{-10}	38
Calcyclin	1–2 mM	90% H ₂ O		7.15×10^{-11}	38
CPA-Ca ₀	1 mM; 6.5	95% H ₂ O	298	1.1×10^{-10}	103
CPA-Ca ₂	1 mM; 6.5	95% H ₂ O	298	1.4×10^{-10}	103

Viomycin	50 mM	90% H ₂ O	303	2.73×10^{-10}	61

CPA-Ca₂ = Calcium loaded carp parvalbumin; CPA-Ca₀ = calcium free carp parvalbumin; MonH·H₂O = monensin free acid form; MonNa = monensin sodium salt; monocyte CP = monocyte chemotactic protein-1; NG_(28–43) = residues 28–43 of neurogranin; rJunLZ = c-Jun leucine zipper; αRNA = α subunit of RNA polymerase; SMKT = salt-mediated killer toxin.

^aIt is possible to scale the diffusion coefficients measured at a particular temperature, *T*, and viscosity, *η*, to standard conditions (i.e., temperature *T*_n and solvent viscosity, *η*_n) using the following relation $D(T_n, \eta_n) = D(T, \eta)[T_n \eta / T \eta_n]$.

^cExtrapolated to infinite dilution.

linearly with the solvent accessible surface.³⁸ Diffusion measurements are now commonly used to determine whether the protein or nucleic acid in a sample exists in the monomeric state (e.g., see Ref.³⁹) and also to provide an independent estimate of rotational diffusion coefficients (i.e., reorientational correlation times) in NMR relaxation studies of protein backbone dynamics.⁴⁰

4.2 Obstruction and Hydration

Obstruction effects have been observed for small molecules such as for H₂ and H₂O moving in protein solutions^{41,42} and for cations in DNA solutions.⁴³ Accounting for the effects of obstruction on the diffusion coefficient of the unbound ligand has also been shown to be important in extracting the true free diffusion coefficient in binding studies.⁴⁴

Protein hydration has been studied as a bulk property by measuring the obstruction effect on water diffusion⁴⁵ and by using diffusion filters to edit out bulk water, thereby allowing identification of individual hydration sites.⁴⁶

Figure 3 Change in lysozyme diffusion coefficients at 298 K and pH 4.6 in the presence of 0.5 M NaCl. The dashed line represents the monomer diffusion coefficient at infinite dilution (i.e., D_1^0) corrected for crowding using the Tokuyama and Oppenheim model.⁸ The lysozyme clearly undergoes a self-association process as the experimental diffusion coefficient is considerably smaller than the crowding effect corrected (with either model) monomer diffusion coefficient. The best fit to the data was obtained using the isodesmic model in conjunction with the Tokuyama and Oppenheim correction (solid line). (Adapted by permission of the American Chemical Society from W. S. Price, F. Tsuchiya, and Y. Arata, *J. Am. Chem. Soc.*, 1999, **121**, 11 503)

4.3 Association

The ability of PGSE NMR to measure diffusion at high solute concentrations makes it a very powerful tool for studying self-association processes in alcohol solutions,⁴⁷ bile salt/phospholipid aggregation,⁴⁸ micelle–peptide association,⁴⁹ the aggregation of β -galactosylsphingosine⁵⁰ and hydrogen bonded calixarene assemblies.⁵¹

The last few years has seen an enormous increase in such studies, including the self-association of human insulin,⁵² BPTI,⁵³ the Alzheimer's related β A4 peptide,⁵⁴ lysozyme¹⁴ and others.⁵⁵ In a detailed study of lysozyme self-association,¹⁴ it was shown that it was crucial to consider the effects of crowding in analyzing the observed diffusion coefficients – otherwise the degree of self-association was seriously overestimated (see Figure 3). Further, if aggregation proceeded to the extent that some of the lysozyme precipitated, it was observed that the measured diffusion coefficient increased since the effective solution lysozyme concentration was lowered and the larger aggregates were removed from the average in equation (7) due to the effects of relaxation-weighting (see Figure 4).⁵⁶

4.4 Binding and Exchange

Diffusion-based binding studies have included protein–ligand interactions such as polyamine–DNA association,⁵⁷ cation–DNA interactions,⁵⁸ protein–surfactant and protein–lipid interactions,^{49,59} hydration water and amide–water

Figure 4 The change in the PGSE NMR-determined diffusion coefficients, $\langle D \rangle_w^C$, of the lysozyme samples (3 mM, $\blacksquare$; 5 mM, $\bullet$; 6 mM, $\blacktriangle$; 7 mM, $\blacktriangledown$) with time at pH 6 and 298 K in 0.5 M NaCl. The open symbols at $t = 0$ h represent the corresponding D_1^C values for these concentrations. The horizontal solid line indicates $D_{\sim 1}^C = 1.5 \text{ mM}$ and the horizontal dashed line indicates $\sim D_1^0$ (see text). (Adapted by permission of the Biophysical Society from W. S. Price, F. Tsuchiya, and Y. Arata, *Biophys. J.*, 2001, **80**, 1585)

exchange rates,^{60,61} and nucleic acid–ligand interactions such as ethidium bromide binding to DNA.⁶² PGSE analysis has also been used to probe the selective complexation of the *cis*- and *trans*-isomers of phenylalanylproline by β -cyclodextrin⁶³ and macrocycle–guest interactions.⁶⁴

¹H PFG DQ experiments can be used to determine the diffusion coefficients of unlabelled molecules by utilizing the gradient pulses at the beginning and end of the DQ excitation period.²¹ Heteronuclear filtered diffusion experiments of peptide binding have also been reported.⁶⁵ X-filter ¹H PFG DQ can be used to identify the molecules in a mixture of unlabelled compounds in solution with a ¹⁵N and/or ¹³C-labelled protein which interact with the protein.⁶⁶

Diffusion based editing has also found an application in characterizing biomolecules in biofluids such as blood plasma,⁶⁷ and PGSE-based binding measurements and spectral editing have now become a major tool in drug screening and combinatorial chemistry where they are often referred to as “affinity NMR”.⁶⁸ Diffusion editing may be used to identify which ligands bind to macromolecules.⁶⁹ In contrast to conventional screening methods, the ligand binding is detected directly, thereby minimizing the observation of false positives. From the NMR perspective, it has the advantage that since only the signals from the ligands are observed, there is no need for isotope labeling. A diffusion-assisted NOE pumping experiment has been used to study the binding of L-ascorbic acid, glucose and salicylic acid to human serum albumin.⁷⁰

5 PRACTICAL ASPECTS OF PGSE MEASUREMENTS

5.1 Introduction

Gradient generation hardware and the commonly used pulse sequences have been covered in the encyclopedia and elsewhere.^{10,19,23,28} In this section, we focus on some recent developments and also on artifacts, how they can be diagnosed and how their effects can be avoided/minimized. With careful experimental technique, it is possible to reduce errors in the measured diffusion coefficient to less than 1%.⁷¹

5.2 Sample Related Problems

5.2.1 Convection

Convection is a source of insidious artifacts in PGSE experiments performed above or below ambient temperature (see Figure 5).^{72,73} While a net flow of spins along the direction of the gradient is clearly indicated by the resulting net phase change, convection currents (see Figure 6),^{74,75} which typically occur along the long axis of the NMR tube, do not produce a phase change since the flow of the spins along the direction of the gradient is exactly matched by the flow in the anti-parallel direction. However, convection causes a cosine modulation of the PGSE signal attenuation (for a single diffusing species),

$$E(g, \Delta) = \cos(\gamma \delta g v \Delta) \exp \left(-\gamma^2 g^2 D \delta^2 \left(\Delta - \frac{\delta}{3} \right) \right) \quad (14)$$

Figure 5 The change in diffusion coefficients versus diffusion time (Δ) for C₁₂E₈ micelles (5 wt%) in D₂O at 45°C measured using the conventional ¹H PGSE STE sequence (■) and the convection compensated double STE sequence⁷⁶ (○). The error bars represent $\pm 2\sigma$. (Reproduced by permission of the American Chemical Society from N. Hedin, T. Y. Yu, and I. Furó, *Langmuir*, 2000, **16**, 7548)

Figure 6 Observation of a twisted nodal plane (a–g) in a sample of DMSO at 311 K. The slices are acquired at different positions along the cylinder. (Reproduced by permission of Academic Press from A. Jerschow, *J. Magn. Reson.*, 2000, **145**, 125)

where v is the velocity of the flow. However, when $v^2 \Delta \ll D$ and $\delta \ll \Delta$, the presence of convection is generally not apparent due to the similarity between the cosine and Gaussian functions. In such circumstances, the data appears to be well described by the usual exponential function giving, to first approximation, an apparent diffusion coefficient of

$$D_{\text{app}} = D + \frac{\Delta v^2}{2} \quad (15)$$

Thus, the presence of convection is suspected when the measured diffusion coefficient of a non-exchanging freely diffusing species increases with Δ . Importantly, whereas the diffusion coefficient depends on molecular size, the flow velocity is common to all of the species in the sample.

Apart from simply improving the temperature control to reduce any temperature gradients, convection can also be minimized or prevented by (i) using a narrower tube; (ii) in the case of some samples, glass wool can be placed in the sample; (iii) surrounding the sample with a fluid of higher heat capacity⁷² or (iv) using specialized pulse sequences (e.g., Ref.⁷⁶ and see Figure 5).

5.2.2 Background Gradients and Radiation Damping

Although the effects of microscopic magnetic inhomogeneities on PGSE measurements are well known and specialized sequences have been devised to counteract the effects, the effects of macroscopic background gradients due to susceptibility differences at the sample interfaces (see Figure 7) have until recently⁷⁷ received scant attention. Similarly, the effects of radiation damping (e.g., see Ref.⁷⁸) on strong signals in PGSE experiments have also been ignored. Both phenomena can lead to the seemingly strange effect of the echo signal growing as the gradient strength increases at low applied gradient strengths and have serious implications for accuracy in determinations of D . For a freely diffusing species, background gradients are often evident as slight concave or convex inflections in the PGSE attenuation curve – depending on the polarity of the applied gradient. The effects of radiation damping can also result in the

attenuation curve being non-linear when plotted in the usual semi-log fashion but, in contradistinction to background gradients, the non-linearity is insensitive to the polarity of the applied gradient.

5.2.3 Transfer of Longitudinal Spin Polarization

The deleterious and often confusing influence of inter-molecular and intramolecular transfer of longitudinal spin polarization by either chemical exchange, spin diffusion or dipolar cross relaxation in STE-based sequences has now been examined in detail.^{79,80} It is noted that problems resulting from these effects can be obviated by the usage of bipolar gradient variations of the STE sequence.

5.3 Problems Related to Gradient Pulses

Five problems related to the gradient pulses that need to be considered in order to obtain accurate diffusion measurements are: (1) the constancy (although more commonly referred to as the linearity) of the applied gradient, (2) gradient pulse mismatch, (3) vibration, (4) eddy currents and (5) gradient calibration. The severity of the latter problems (2)–(4) increases with higher amplitude gradient pulses such as would be used when measuring very large (i.e., very slowly diffusing) biomolecules, solids or attempting to use a short Δ to obviate relaxation-weighting problems. Eddy currents have previously been treated in detail in the encyclopedia and elsewhere^{10,81} and will not be discussed here.

5.3.1 Gradient Constancy

The analysis of the PGSE experiment is simplified if the sample volume is contained within the constant region of the gradient, although small deviations do not generally cause serious errors.⁸² Gradient coils generally only produce a constant gradient over a small part of the sample volume, thus, it is necessary to restrict either the volume from which the NMR signal is acquired such as by making the first pulse in the PGSE sequence slice-selective (e.g., Ref.⁸³) or by simply restricting the volume of the sample. This latter approach has been made particularly simple with the advent of susceptibility matched NMR tubes. The effective sample volume is also restricted to a significant extent by the size of the rf coils, however, this volume is often larger than the volume of constant gradient.

5.3.2 Gradient Mismatch and Vibration

Gradient pulse mismatch, vibration/sample movement with respect to the gradient coils and eddy currents can all produce confusingly similar effects.⁸⁴ Gradient pulse mismatch and vibration/sample movement in the PGSE experiment for the case of a freely diffusing species can be modeled by rewriting the PGSE attenuation equation in the short gradient pulse limit including a phase-shift, ϕ , due to the effects of a gradient (magnitude) mismatch, Δq (i.e., it is assumed that Δq is parallel to $\mathbf{q}$ which is directed along the z -axis) and sample movement, Δz , between the first and second gradient pulses (NB in Δq and Δz , ‘ Δ ’ denotes differential) thereby

Figure 7 Simulation of the background gradients in a standard NMR tube. The simulations were performed using a radius of 4.5 mm and a length of 6.2 mm and setting $\chi_{\text{air}} = 1$ and $\chi_{\text{water}} = 0.999991$. Each contour reflects a 0.5 ppm change in the field. (Reproduced by permission of Academic Press from W. S. Price, P. Stilbs, B. Jönsson, and O. Söderman, *J. Magn. Reson.*, 2001, **150**, 49)

obtaining^{84,85}

$$E(q, \Delta) = \underbrace{\int P(Z, \Delta) e^{i2\pi q Z} dZ}_{E_{\text{diff}}(q, \Delta)} \underbrace{\left\{ e^{i2\pi(q+\Delta q)\Delta z} \right\}}_{\exp \phi(\Delta z)} \times \underbrace{\int \rho(z_1) e^{i2\pi \Delta q z_1} dz_1}_{E_{\text{phase}}(\Delta q)} \quad (16)$$

where $P(Z, \Delta)$ is the average propagator,⁸⁶ $E_{\text{diff}}(q, \Delta)$ is the diffusive attenuation (i.e., equation (6)), $\exp \phi(\Delta z)$ is the residual phase-shift due to vibration/sample movement, is position independent and can be removed by individually phase-correcting each spectrum or by computing the absolute value spectrum.⁸⁵

The third term (i.e., $E_{\text{phase}}(\Delta q)$) is the residual phase-twist resulting from the gradient pulse mismatch and is, for the case of a cylindrical sample of length l , centered in the gradient,

$$E_{\text{phase}}(\Delta q) = \frac{\int_{-l/2}^{l/2} e^{i2\pi \Delta q z_0} dz_0}{l} = \text{sinc}(\pi \Delta q l) \quad (17)$$

Even extremely small mismatches can cause a severe loss in echo signal intensity. If Δq is taken as being a fixed proportion of q (not an unreasonable assumption), then $E_{\text{phase}}(\Delta q)$ is a damped oscillation with the degree of damping and the periodicity being exquisitely sensitive to the degree of mismatch. In extreme cases, this has the potential to produce artifactual ‘diffraction’ peaks.

Phase-based artifacts can be detected by performing measurements on a freely diffusing sample with a very small diffusion coefficient (e.g., large polymer) using the same experimental parameters (i.e., q and Δ) to be used in the intended experiment. Their removal, however, is more troublesome. The possibilities include: (1) improving the gradient pulse generation, (2) empirically matching the gradient pulse pairs, (3) using the imaging based Modulus Addition using Spatially Separated Echo spectroscopy (MASSEY) sequence approach,⁸⁵ (4) prefixing a number of Δ -spaced gradient prepulses⁸⁷ to increase gradient pulse reproducibility or (5) using shaped gradient pulses which are easier to generate reproducibly. The last two choices are the most convenient and additionally they retain spectral information. The addition of gradient prepulses can also help to alleviate eddy current problems as they have the effect of balancing the eddy current distortions in the τ -periods. In addition to reducing both mismatch and eddy current problems, shaped gradient pulses, due to their slower rise and fall times, are also less likely to produce vibration of the sample/probe.⁸⁴

5.3.3 Gradient Calibration

There are a number of methods for gradient calibration including: (1) theoretical coil calculation, (2) performing a measurement with a sample of known diffusion coefficient (see Ref.⁸⁸ for a list of suitable standards), (3) shape analysis of the spin-echo and one-dimensional images and (4) intentional gradient mismatch. These methods have been reviewed in detail elsewhere,¹⁰ and methods for calibrating gradients for stray field (STRAFI also known as supercon-fringe field steady-gradient spin-echo) studies have recently been considered.⁸⁹

In practice, calculating the gradient from the coil dimensions and the applied current results in an error of about 10%, due primarily to interactions with nearby metal in the probe. The standard sample technique is particularly useful since non-ideal gradient behavior (e.g., non-constancy) is to some degree compensated for by being incorporated into the apparent calibration value determined. It is important, however, that the experimental conditions (i.e., sample shape, delays, pulse lengths, gradient strengths, etc.) used for the calibration follow closely those used in the subsequent experiments. This method of gradient calibration requires excellent temperature control and is further limited by the need to have a compound containing a nucleus that can be observed with the probe at hand and with a similar diffusion coefficient.

Using a sample with a single resonance (e.g., H_2O), the gradient strength can also be calculated from the echo shape from a sample of known geometry since both the observed FID and spectrum will reflect both the gradient and the shape of the sample. Since the number of spins is constant along the cylinder axis, the absolute value of the Fourier transform of the signal must be rectangular with a ‘line width’, Δv (Hz), given by

$$\Delta v = \frac{\gamma g l}{2\pi} \quad (18)$$

If the transmitter offset is placed at the resonance frequency of the sample (i.e., in the absence of the gradient) then, if the sample is correctly centered in the gradient, the gradient broadened spectrum will expand symmetrically around the transmitter offset as the gradient strength is increased. This method requires that the length of the sample containing cell be known accurately and the final calibration will have an error of less than 5%. Two virtues of this method are that the calibration can be performed without any knowledge of the sample diffusion coefficient and, so long as the dimensions of the container holding the sample are not too temperature sensitive, it can be used to cross-check that the gradient strength is not temperature dependent. However, this method has a limited range of applications since, for anything more than modest gradients, the gradient broadened spectrum is larger than the maximum spectrometer bandwidth.

The gradient mismatch approach is based on the notion that the time displacement of the echo maximum caused by the intentional mismatch of gradient pulses shifts in a very well-defined way allowing the gradient to be calibrated (vide supra).

The large steady gradients used in STRAFI techniques can be calibrated using the separation in sensitive planes from a heteronuclear sample (e.g., ^1H and ^{19}F) and from field profiling by following the change in resonance frequency with position in the gradient of a single signal.

5.4 Sequence Developments

5.4.1 Solution State

Heteronuclear PGSE sequences which invoke polarization transfer from protons to the heteronuclei (e.g., ^{13}C or ^{15}N) have been developed for macromolecular studies.^{65,90} and there has also been considerable interest in the development of sequences for the selective editing of spectra based on diffusion coefficient differences and for determining exchange.^{21,46,68,69,91} A diffusion assisted NOE-pumping experiment has also been proposed in which a diffusion experiment

is prefixed to an NOE experiment which is useful when the difference in diffusion coefficients between the binding and non-binding ligands is insufficient to allow editing solely on the basis of the difference in diffusion coefficients.⁷⁰ There has been some interest in the use of nonlinear spin echo based diffusion measurements.⁹²

Although technically more difficult, there are numerous reasons for desiring large applied gradients including being able to measure slower diffusion (i.e., in solids), but also to use shorter Δ -values to obviate the problems associated with relaxation-weighting and convection. The availability of stronger gradient pulses also increases the applicability of Hahn-echo based PGSE sequences which can be important since they obviate the problems resulting from cross-relaxation which can occur when performing measurements on macromolecular systems with STE based sequences. The larger available gradient pulses also allow diffusion measurements in liquid isotropic systems to be performed on quadrupolar nuclei with short relaxation times such as ^{17}O .⁹³

5.4.2 Near Solid State and the Solid State

The applicability of standard PGSE methods to near solids and solids is severely limited due to the short relaxation times (usually less than 1 ms) which leave insufficient time for the application of the gradient pulses. True solids present additional difficulties due to the presence of (unaveraged) anisotropic interactions (e.g., dipole–dipole). Efforts to circumvent the relaxation time difficulties have proceeded along two paths: (1) Generation of larger gradient pulses with short settling times in PGSE experiments or the use of the extremely large gradients in the stray field of superconducting magnets in steady gradient diffusion experiments and (2) modifications to the PGSE sequence to average out the nuclear spin interactions and thereby lengthen the available time to perform the PGSE sequence.⁹⁴ The application of very high gradients to diffusion measurements has recently been reviewed.⁹⁵

5.4.2.1 Large Gradient Pulses and Stray Field

Gradient coils have now been designed to generate pulsed gradients up to 52 Tm^{-1} and have allowed the study of samples with T_2 s of less than 1 ms.⁹⁶ Using gradients of this magnitude, diffusion coefficients down to $7.5 \times 10^{-16}\text{ m}^2\text{s}^{-1}$ have been measured.⁹⁷

The available gradient strengths in STRAFI have been increased up to 180 Tm^{-1} by using superconducting coils in an anti-Helmholtz arrangement. However, STRAFI measurements suffer from poor signal-to-noise as the rf pulses can only excite a thin slice of the sample and, because the echo is acquired in the presence of the gradient, spectral information is lost. Further, since this is a steady gradient experiment, the delays in the sequence have to be lengthened to probe the diffusion process, and consequently attention must be paid to removing relaxation weighting effects⁹⁸ in addition to the problems resulting from cross relaxation, spin diffusion and chemical exchange.

5.4.2.2 Non-Vanishing Dipolar Decoupling

Early attempts to measure diffusion coefficients in samples with static dipolar couplings used PGSE sequences based on nematic and solid echoes (also relevant to quadrupole

broadened spectra). During the past decade, numerous sequence modifications have been presented including dipolar decoupling (both homo and heteronuclear) which not only extends the periods in which the gradients can be applied but also prevents spin diffusion during the gradient application.^{80,99–101} By combining dipolar decoupling with STRAFI, diffusion coefficients down to $3 \times 10^{-16}\text{ m}^2\text{s}^{-1}$ have been reported.⁹⁹

1 INTRODUCTION TO RELAXOMETRY

The demonstration half a century ago of proton NMR in liquid water by Bloch et al.^{1,2} and in solid paraffin by Purcell et al.³ came one year after Rabi received the Nobel Prize (1944) ‘for his discovery of a resonance method for recording the magnetic properties of atomic nuclei’; i.e., for discovering NMR. Rabi and his associates had worked with radiofrequency (rf) resonant transitions in atomic and molecular beams since the mid-1930s.^{4,5} By the time of the discoveries of Bloch and Purcell, the proton g -value was known to six-figure accuracy,⁶ the concept and language of rotating frames were in place,^{7–9} and wartime technological advances were such that it was clear that a proton NMR signal could be seen in condensed matter well above noise at the then attainable fields ‘provided that thermal equilibrium could be established in a reasonable time’.³ The major unknown was the longitudinal relaxation time T_1 of protons, a parameter that has no relevance in beam measurements; early estimates for proton relaxation times for the condensed state were minutes to hours.¹⁰ Bloch et al. used ‘paramagnetic catalysts ... to accelerate the establishment of thermal equilibrium’;¹ they added trace amounts of ferric nitrate to their water samples.² In addition they used the ‘nuclear induction’ signal generated by proton magnetization precessing in the transverse plane to help circumvent problems associated with a long T_1 . Purcell et al. measured absorption using an rf bridge and a very low power level, such that ‘the absorption would persist for hours regardless of the relaxation time, once thermal equilibrium had been established’.³

A fairly complete theory of proton relaxation in diamagnetic liquids, e.g. water and its mixtures with glycerol, and in solutions with trace millimolar amounts of small paramagnetic solutes was developed in short order.^{11–14} The basic concept is that of ‘motional narrowing’ of the interaction ω_{int} (the

intrinsic uncertainty width) that induces relaxation in liquid systems. The rapid Brownian motion of liquid molecules reduces the uncertainty width by the factor $\omega_{\text{int}}\tau_c \ll 1$, where τ_c is a correlation time that characterizes the timescale of the Brownian fluctuations. The result, in the limit of the external field B_0 approaching zero, is

$$1/T_1 = 1/T_2 \simeq 6\omega_{\text{int}}(\omega_{\text{int}}\tau_c) \quad (1)$$

for the interaction of two identical nuclei with spin of $\frac{1}{2}$. For protons of water the fluctuating interaction is a sum over the magnetic dipolar interaction of all pairs of protons (dominated by the intramolecular water proton–proton interaction of about 5 Oe). Where ω_{int} ($\sim 10^5 \text{ s}^{-1}$) is the angular Larmor precession frequency ω_L of a proton in this interaction field and τ_c ($\sim 3 \times 10^{-12} \text{ s}$ at 25 °C) is determined by the Brownian reorientational time of a water molecule since the magnetic interaction of two protons is a function of their spatial orientation. For water deuterons, the fluctuating interaction is that of the nuclear quadrupolar moment with the gradient of the electric field at the nucleus. For deuterons ω_{int} is three times larger than for protons, leading to intrinsic relaxation rates for deuterons that are ten times greater than for protons in analogous diamagnetic systems. The six-fold lower g -value of the deuteron makes magnetic interactions of deuterons, e.g. with proton and electronic moments, 40 times less than the analogous proton interactions and generally ignorable. However, for both protons and deuterons of solvent water, any diamagnetic solute (or other variable, such as temperature) that slows the motion of a water molecule, on average, reduces the effect of motional narrowing and thereby increases relaxation rates at low fields by comparable factors. Both $1/T_1$ and $1/T_2$ decrease with increasing B_0 , with a Lorentzian dispersion centered near $\omega_L\tau_c = 1$. Hence there is a need for measurements of relaxation rates over a wide range of B_0 if relaxation mechanisms are to be studied effectively.

Early applications of proton NMR were directed towards an understanding of the molecular dynamics of water molecules in water solutions, i.e. the nature of microscopic viscosity, self-diffusion of solvent, Brownian motion of hydrated paramagnetic solutes and the lifetimes of solute–solvent complexes. The data were the relaxation rates of the majority solvent protons, as a function of temperature and, to the extent possible, as a function of the applied field B_0 , since available NMR resolution and signal intensity were inadequate to resolve structure in the water line and certainly inadequate to detect solute nuclei. Hence the relaxation rates of solvent water nuclei served as indicators of solvent interactions with solute. With advances in magnet technology and electronics, ‘higher resolution’ NMR became possible, and research emphasis shifted to measurements of proton spectra in water solutions of relatively small solutes. Increasingly higher fields, superconducting magnets, signal averaging and Fourier transform methodologies have brought applications of high-resolution NMR to 600 MHz and beyond, with multidimensional high-field spectroscopy now routinely applied to solute polymers, polypeptides, and increasingly larger proteins.

As spectroscopy has advanced, so has ‘relaxometry’, the field—in analogy with spectroscopy—that includes the measurement and theory of, and instrumentation (‘relaxometers’) for, increasingly sophisticated investigations of relaxation rates

of (mainly) water nuclei in progressively more complex systems, both diamagnetic and paramagnetic. ('Relaxometry' and 'relaxometer' are terms coined by the author in 1983.) Initially, as noted, relaxometry was the approach of choice for the study of water dynamics in simple solute-solvent systems. When early improvements in resolution of NMR signals made possible the direct study of spectral lines of small solutes, relaxometry was applied, typically, to solutions of paramagnetic metalloproteins, including their complexes with small substrates and activators; the area now called 'bioinorganic chemistry.' With further improvements in NMR resolution, and the advent of proton spectroscopy of small protein solutes, relaxometry became the approach of choice for studying the dynamics of water in progressively more complex systems, including tissue. This was aided by the development of a field-cycling relaxometer,¹⁵ based on the early ideas of Redfield,¹⁶ that could record the dependence of $1/T_1$ on B_0 (called a nuclear magnetic relaxation dispersion (NMRD) profile) automatically, under computer control, over almost four decades of B_0 . The discussion of the dynamics of water in biological systems presented here is based on NMRD data obtained with our field-cycling relaxometers.

In magnetic resonance imaging (MRI) in clinical diagnostic radiology, an increasingly important application of high-resolution NMR, the image generated is a three-dimensional spatial representation of tissue dependent relaxation rates of the volume of interest. Most tissues contain about the same amount of water, ostensibly for reasons of osmotic equilibrium, so MRI would be ineffectual unless signal intensity was weighted by some parameter other than (water) proton density. This has stimulated research on relaxation processes of water protons in complex systems, including several different tissues, and their model systems. We now have a relatively complete molecular theory of relaxation of water protons in tissue¹⁷ (which is mostly water and immobile protein), as well as in solutions of proteins, both native and immobilized; the latter is an excellent model system for the relaxation behavior of water protons in most tissues. Much has been learned about the dynamics of water molecules in these macromolecular biological systems, particularly regarding the details of dynamic and magnetic protein-water interfacial interactions and, to a lesser extent, lipid-water interfacial interactions. Pertinent data, chosen to support the generalizations made here regarding water dynamics, are collected in this article. The theory and a short discussion of the instrumentation are given in another article in this Encyclopedia (*Relaxometry of Tissue*).

The emphasis throughout this article is on broad generalizations regarding the behavior of water in biological systems, concepts that have come from relaxometry investigations. In particular we argue for the view that water, even in complex tissues, is no more structured than is pure water, and that the water molecules in each have comparable mobility and diffusivity. In essence, solvent molecules, as regards their molecular dynamics—which in turn determines nuclear relaxation rates—really do not learn about the presence of small or macromolecular solute until solute and solvent molecules collide physically, essentially at their hard-core radii. The overall water dynamics are altered imperceptibly by these collisions and associations. However, relaxation rates are very sensitive to the details of these collisions—because of the possibility of massive, although momentary, lengthening of τ_c —and to the possibility of diffusion of proton magnetization in immobile

macromolecules. The far-ranging result is a very rich set of phenomena that can be encompassed by a simple picture of water dynamics in biological systems.

2 PROTEIN-WATER INTERFACES

2.1 Water Deuteron $1/T_1$ NMRD Profiles in Systems of Immobile Protein

The data shown in Figure 1 are perhaps the most telling for the major generalization made here. They include $1/T_1$ NMRD profiles of deuterons in water-protein systems in which the protein is not free to rotate:¹⁸ two samples of bovine serum albumin (BSA, 68 kDa) in water at relatively low concentrations, initially liquid, in which the solvent protein was immobilized by chemical cross linking; a third, otherwise identical sample, in which the macroscopic viscosity of the solvent was increased seven-fold by the addition of dextran before cross linking; and a sample of cross-linked bovine carbonic anhydrase (BCAB, 30 kDa), about one-half the molecular weight of BSA. (The solid curve is an empirical fit to the data for these four samples, for clarity.) A fifth sample was powder,¹⁹ BSA hydrated to 50% by weight (corresponding to about four water hydration layers per BSA molecule). The profiles are all normalized to their low field values after

Figure 1 $1/T_1$ NMRD profiles of water deuterons for five samples of immobile protein, all normalized to the same vertical scale after subtraction of $1/T_1$ of solvent at each temperature. (∇, Δ) 4.8 wt %, chemically cross-linked BSA (68 kDa) at 35 °C, the first (∇) containing 70 mg ml⁻¹ dextran, which increases the macroscopic solvent viscosity by a factor of 7.4. ($\square$) As (Δ), but with 10% BSA. ($\circ$) 3 wt % BCAB (30 kDa) at 25 °C. The solid curve is an empirical fit to the profiles of these four samples, with $\nu_c = 0.097$ MHz. The curve is for visual clarity, and has no theoretical importance in the present context. The low field rates, above the solvent background are, respectively, 42, 44, 75, and 24 s⁻¹. ($\bullet$) Powder, dried BSA rehydrated to 50 wt % water, at 18 °C.¹⁹ (Reproduced by permission from S. H. Koenig, R. D. Brown III, and R. Ugolini, *Biophys. J.*, 1988, **53**, 77)

subtraction of the background rate of pure water, to show that the normalized functional forms of the five profiles of these disparate samples are essentially the same. Deuterons were measured, rather than protons (although their signal is smaller than for protons and more difficult to obtain accurately), because their relaxation is predominantly electric quadrupolar. As a result, changes in their relaxation rates induced by solute arise only from (subtle) alterations of the molecular dynamics of the water solvent, uninfluenced by magnetic interactions. What do such data indicate?

The five samples all appear to be relatively solid, the cross-linking (in four of them) creating an extended network of immobile protein which entrains solvent water by capillarity. However, the proton NMR signals from the water deuterons in all the samples indicate that essentially all the water is highly liquid and mobile. That the normalized profiles of the 4.8 and 10% BSA samples have the same form, after correction for the uniform water background ($\sim 2 \text{ s}^{-1}$ at 35°C , which is a significant fraction of the observed rates, particularly above $\sim 0.5 \text{ MHz}$), means that the intrinsic $1/T_1$ contribution of the solvent water when not in interaction with the protein (i.e. τ_c , and therefore the Brownian rotation of the bulk water) is unaltered by the presence of solute protein. Similarly the presence of dextran in one sample, which increases solvent viscosity seven-fold, neither alters the form nor the magnitude of the NMRD profile. The correction for water background is essentially that for pure water, assumed to be unaltered by the large change in macroscopic viscosity. The data are similar for carbonic anhydrase, which shows that BSA is not unique in its surface properties. The most intriguing results are those for BSA hydrated powder. The very existence of a signal shows that most of the water in the four monolayers is highly mobile, i.e. the dynamics of a two-dimensional array of four monolayers of water molecules abutting a protein interface is very much like that of pure three-dimensional water.

The major question is what the inflection frequency ν_c (Figure 1) (at the half magnitude $\sim 0.1 \text{ MHz}$) represents. It corresponds²⁰ to $\tau_c \simeq 1/11\nu_c$, or $\tau_c \simeq 1 \mu\text{s}$ because of factors of 2π and the contributions of both single- and double-quantum transitions to relaxation. We have only recently^{17,18} been able to associate this correlation time with the lifetime of a class of water molecules held rigidly at two sites (rounded) per BSA molecule (one monolayer corresponds to 700 water molecules). It was argued that these two water molecules are bound in a very specific configuration by four hydrogen bonds, an accident of the geometry of protein surfaces. The conjecture is that one proton of a coordinated water binds symmetrically to the two oxygen atoms of a deprotonated surface carboxylate, attached by two hydrogen bonds. The other proton could bind similarly to a nearby carboxylate or, as found recently in a neutron diffraction study of myoglobin (B. Schoenborn, private communication), symmetrically between the deprotonated nitrogen atoms of two surface histidines. An estimate of the water lifetime, obtained from the energy required to break four such bonds ($2.6 \text{ kcal mol}^{-1}$ or $\sim 5 \text{ kT}$ each) and the infrared stretching frequency of such bonds ($\sim 3 \times 10^{12} \text{ s}^{-1}$), are consistent with the τ_c evident in Figure 1.

The foregoing leads directly to a 'two-site rapid exchange' view of relaxation in these systems, which we favor: water

molecules bind at specific protein–water interfacial sites, at which the slowed motion increases their relaxation rates *in situ*. The resident lifetimes should be shorter than the interfacial T_1 values or the effect of binding will be limited by 'slow exchange'. Because of their quadrupolar relaxation, binding of deuterons will not alter the strength of the interaction that relaxes them, but will change the correlation time. The extent of this change for the samples (Figure 1) is known. Increases in τ_c from 3 ps in solution to $1 \mu\text{s}$ when bound leads to only two bound water molecules in rapid exchange being necessary to explain these data. It follows that all the other interfacial water molecules must have much shorter lifetimes. This view implicitly leads to an approach that readily allows—indeed requires—the various water molecules that hydrate protein to be grossly inequivalent. Some authors have taken exception to this in explaining water relaxation in protein and colloidal systems, noting without argument that the bound 'state comprises an unphysically small number of water molecules',²¹ and have looked for mechanisms in which all interfacial water molecules behave identically at all interfacial locations, altered in their motion by the imposition of a very small order parameter with a long relaxation time, by unknown mechanisms. The data shown in Figure 1 and the discussion given in the next section make this view untenable; the small number of long-lived interfacial water molecules is indeed the physical reality.

2.2 Water Deuteron and Proton $1/T_1$ NMRD Profiles in Solutions of Mobile Protein

Figure 2 shows both deuteron and proton $1/T_1$ profiles of solutions of native (mobile) carbonic anhydrase for solvents of differing isotopic composition.²² For deuterons the profiles are independent of whether water is partially or fully deuterated. This is as expected, since a deuteron is relaxed by very local interactions of its quadrupole moment with the local electric field gradient. A second point of note is that the quasi-Lorentzian form of the profile, although much like that of immobile carbonic anhydrase (Figure 1) has $\nu_c \simeq 4 \text{ MHz}$, i.e. 40 times higher for mobile than immobile protein. It has been known for some time,^{23,24} and demonstrated for almost three decades of molecular weight,²⁰ that ν_c for mobile proteins is determined in the main by the Brownian rotation of solute and is calculable from Stokes' law.

In contrast to the deuteron profiles, those for protons are dependent upon whether a water proton has another proton as its neighbor. However, this dependence is much less than the expected linear dependence on $1/T_1$ (including the solvent background) with proton dilution. This is the most direct evidence that interactions between solute and solvent protons ('cross relaxation'²²) contribute to solvent proton relaxation. The extent of the contribution of cross relaxation to each sample can be inferred from the broken curves, which show the proton $1/T_1$ profiles predicted from the deuteron results, assuming no cross relaxation for protons. It is evident that cross relaxation and 'hydrodynamic' relaxation (for protons) are comparable for a protein of 30 kDa , even with undeuterated solvent.

Figure 2 $1/T_1$ NMRD profiles of water deuterons (open symbols) and protons (filled symbols) for samples of 4.1 mM native (mobile) BCAB (30 kDa), at 5 °C. The data are expressed as relaxivity, the value of $1/T_1$, with the solvent contribution subtracted, per mM of solute protein. For the deuteron profiles, the water was 93% (○), 85% (□), 60% (△), and 20% (▽) deuterated. The solid curve is a fit to these profiles, which are seen to be independent of solvent isotopic composition. The broken curves are the profiles expected for protons, based on the deuteron results, taking into account only the different intrinsic relaxation rates of deuterons and protons in pure water. For the measured proton profiles, the water was 100, 80, 50, and 15% protonated. In each case, the relaxivities were significantly above the broken curves, indicating a significant contribution to the relaxivities arising from interactions between solute and solvent protons (cross relaxation). (Reproduced by permission from S. H. Koenig, R. G. Bryant, K. Hallenga, and G. S. Jacob, *Biochemistry*, 1978, 17, 4348)

2.3 Conjectured Classes of Other Protein–Water Interfacial Binding Sites

We have argued for a class of interfacial binding sites with water molecules, held in place by four hydrogen bonds, having $\tau_M \approx 1 \mu\text{s}$. What then of three bonds, two bonds, etc? Table 1 gives our estimate of the interfacial lifetimes of these other configurations and the associated values of ν_c when protein rotation can be ignored. Each added bond is estimated to increase τ_M by a Boltzmann factor of about 50. What follows are data that support the table entries. The picture that emerges of the nature of the protein–water interface in solution is one of several (four) classes of water-binding site, each with a narrow and identifiable range of water lifetimes and increasing in number as the stereochemical requirements become less restrictive.

2.4 Influence of Protein Molecular Weight on Water Proton $1/T_1$ NMRD Profiles

Figure 3 shows proton $1/T_1$ profiles²⁴ for solutions of the same total protein content, but with molecular weights ranging from 14 to 450 kDa. For water molecules with $\tau_M \approx 1 \mu\text{s}$ ($\nu_c \approx 0.1 \text{ MHz}$), this lifetime is sufficiently long to sense the protein rotation of all the proteins shown in the figure. It is only when the molecular weight becomes about 10 times greater than that of hemocyanin ($\sim 5000 \text{ kDa}$) that Brownian

Table 1 Values of the Lifetime τ_M of a Water Molecule bound at a Protein–Water Interface when Held by n Hydrogen Bonds, Near 25 °C^a

n	τ_M	$\nu_c = \frac{1}{2}\pi(\sqrt{3})\tau_M$ (MHz)	B_0 (T)
4	1 μs	0.1	0.0024
3	20 ns	5	0.12
2	400 ps	250	6
1	8 ps	12500	300

^aFor immobile protein, τ_M becomes the correlation time for interfacial interactions, leading to an inflection in the NMRD profile at nuclear Larmor frequency ν_c , corresponding to a magnetic field B_0 for protons.

rotation is too slow to be sensed by these long-lived water molecules,²⁵ and so this is not a concern here. However, τ_M for three bonds was found¹⁷ to be 23 ns in a particular case, which corresponds to $\nu_c \approx 4 \text{ MHz}$, a field well above the major dispersion of hemocyanin. A contribution from such shorter lived sites is clear in the hemocyanin data, shown here for proton profiles of a native mobile protein for the first time. The two solid lines represent true Lorentzian dispersive contributions to $1/T_1$, ostensibly the 1 μs and 20 ns sites, the latter with 5.2 times the population, and with values of ν_c of 0.4 and 4.0, respectively. For the lower field curve the dispersion relates to protein rotation, whereas for the higher field curve the dispersion arises from τ_M . The two curves sum to the open symbols ($\surd$), which clearly represent the data quite well.

The existence of three-bond sites has been argued for recently¹⁷ (see *Relaxometry of Tissue*), based mainly on extensive theoretical analysis of proton profiles of cross-linked BSA in highly deuterated solutions, to emphasize cross relaxation, but has also been deduced from analyses of data such as those shown in Figure 1. However, the density and lifetime of this three-bond class of sites are such that their contribution to relaxation can only be deduced with some certainty in special circumstances, including the high molecular weight hemocyanin (Figure 3), and then only if the existence of such sites is suspected.

The four- and three-bond sites still leave 97% of a hydrogen monolayer unaccounted for. Two-bond sites should have $\nu_c \approx 250 \text{ MHz}$ and $\tau_M \approx 400 \text{ ps}$, as in Table 1. Extensive arguments were given some time ago from the first NMRD profiles of protein solutions for sites with these characteristics:²³ they are ostensibly associated with water molecules surrounding polar groups at the protein–water interface, comprising about one-third of a hydration monolayer.²⁶ Quite recently, results of multidimensional NMR at 600 MHz were reported²⁷ for a very small protein (7 kDa), bovine pancreatic trypsin inhibitor—a protein too small to have any four-bond sites and few three-bond sites. The finding was that no water lifetimes were longer than about 300 ps, which is consistent with the foregoing discussion, although the fraction of interfacial water molecules that might exchange more rapidly was not determined.

The lifetime of a water molecule held by a single bond (Table 1) should be about 8 ps. This is only three times greater than the rotational relaxation time of a free water molecule at 25 °C. Even a monolayer of such bonds in a concentrated protein solution would contribute minimally to $1/T_1$, and be difficult to identify. It should be emphasized that it is very difficult to obtain an estimate of this value from the literature. An assiduous search was made earlier, when the relaxivity of

Figure 3 $1/T_1$ NMRD profiles of water protons in solutions of native proteins of various molecular weights, at a fixed concentration of 50 mg ml⁻¹, at 25 °C: (■) hemocyanin (450 kDa); (○) immunoglobulin G (160 kDa); (●) yeast alcohol dehydrogenase (160 kDa) (▲) bovine carbonic anhydrase (30 kDa); (▼) lysozyme (14 kDa). The broken horizontal line is the solvent background rate. The two solid curves associated with the hemocyanin data are Lorentzians, the sum of which (□) matches the data; they have ν_c values of 0.8 and 4.0 MHz. The lower field Lorentzian is, in our view, associated with exchange of water molecules bound at sites with lifetimes of about 1 μ s, i.e. sufficiently long to sense the Brownian rotation of solute, and the higher field Lorentzian is associated with sites of lifetimes of about 20 ns, which is sufficiently short that the lifetime determines ν_c . (Reproduced by permission from K. Hallenga and S. H. Koenig, *Biochemistry*, 1976, 15, 4255)

nitroxide radicals was studied in some detail.²⁸ There is clearly no formal inner coordination sphere for these solutes, but there was a question of whether they formed short-lived hydrogen-bonded complexes with solvent water. The conclusion was that any such complexes had to have lifetimes less than the rotational relaxation time of the nitroxide (≈ 500 ps).

Relaxation of water deuterons by montmorillonite clays, which contain large lamellar particles with atomically smooth surfaces and oxygen atoms pointing to the water, were studied²⁹ in some detail to investigate interfacial interactions in these well-defined systems. Deuterons were measured to minimize artifactual contributions from possible paramagnetic impurities and interlamellar spacing was adjusted by dilution with solvent. The finding was a small contribution to $1/T_1$ that could be explained by a monolayer of water molecules being slowed in their rotation by a factor of about 5. We suggest that this could arise from the formation of a single hydrogen bond between each interfacial water proton with an uncharged surface oxygen atom. The major point is how little the motion of water is influenced by surfaces that have no special sites for enhancing solute–solvent interactions.

The power of computers and computing algorithms has advanced significantly during the last decade. Relevant interatomic and intermolecular interaction potentials are also well known, so that the molecular dynamics of water in

relatively complex systems can be computed reliably to times approaching several hundred picoseconds. In a recent computation³⁰ of water interacting with myoglobin (15 kDa), the highly local self-diffusion constant of water was calculated near to the solute–solvent interface. The major result, as read by this author, is how little water is affected by the protein. Major questions would be whether the local diffusion constant is two- rather than three-fold different from its value in bulk water. There is no structure induced in the water, either temporal or spatial, other than that demanded by hard-sphere geometry, certainly to first order. Unfortunately, τ_M values for our three- and four-bond sites are far longer than the limits of such computations, although there are a few pockets of depressed diffusion that hint at the influence of these sites on local water dynamics.

2.5 Water Proton $1/T_1$ NMRD Profiles in Systems of Immobile Protein

The picture becomes complete when proton $1/T_1$ NMRD profiles of immobilized protein systems are also considered. Figure 4 shows¹⁸ that, in contrast to deuterons, for protons the functional form of the profiles is dramatically altered by immobilization. Moreover, the profiles become like those of tissue, most of which have the same form but differ in magnitude.²⁰ Without going into details of theory and mechanism, which are covered elsewhere in this Encyclopedia (*Relaxometry of Tissue*), we note that—whether measured in a relaxometer or imager, or whether one measures $1/T_1$, $1/T_2$, or $1/T_{1\rho}$ at any field or temperature—it is not possible to

Figure 4 $1/T_1$ NMRD profiles of water protons of three samples with essentially the same (~ 20 wt %) solids content, at physiological temperature: human spleen (solid curve), native bovine serum albumin (○), and the same sample immobilized by chemical cross linking (●). Such cross-linked protein is an excellent model system for most tissue, so much so that the two cannot be distinguished by measurements in either a relaxometer or an imager¹⁷ (Reproduced by permission from S. H. Koenig, R. D. Brown III, and R. Ugolini, *Magn. Reson. Med.*, 1993, 29, 77)

distinguish a sample of, for example, cross-linked BSA from a typical tissue (exclusive of white matter and adipose tissues, both with different but significant lipid contributions). A ready inference is that water is not compartmentalized in tissue on a relaxation timescale, otherwise one would see tissue-specific effects. Most protein in tissue, which usually contains no more than protein and water, is also immobile.

The difference in functional form between proton and deuteron profiles in immobile systems (see Figures 1 and 4), but not mobile systems (Figure 2), must relate to the presence and absence, respectively, of cross relaxation for these two nuclei plus an increase in the importance of cross relaxation in immobilized systems. Briefly, the change relates to the mobility of proton magnetization in immobile systems, for which relaxation is like that in the solid state, and its absence in liquid state systems, where motional narrowing holds. For the solid state mutual spin flips of neighboring protons serve to transport Zeeman energy without loss of magnetization, since there are few fluctuations to relax the magnetization to the 'lattice'. Thus spin diffusion in the solute and chemical diffusion in the solvent generate a combined system that can be modeled as two Zeeman reservoirs. Each of these has spatially uniform magnetization which is coupled through interfacial interactions that transfer energy between the reservoirs. For protein–water systems the four-bond sites serve not only as the dominant sites for such transfer but, because of the relaxation that occurs at these sites, also serve as the major sites for relaxation of the total Zeeman energy with the thermal energy of the sample¹⁷ (see also *Relaxometry of Tissue*). For the liquid state, appropriate for mobile protein, the situation changes dramatically. Unlike the solid state case, for which mutual spin flips derive from the precession of a proton in the static interaction field, mutual spin flips arise from the zero quantum transitions generated by a fluctuating interaction field (ω_{int}). However these also generate single- and double-quantum transitions that relax the diffusing magnetization.²⁰ The net result is that the Zeeman energy of most of the solute is not in good contact with solvent and the potential amount of cross relaxation is reduced. In fact, as can be seen from Figure 2, the contributions of cross relaxation and hydrodynamic relaxation to $1/T_1$ of protons is comparable. That is, each proton of a water molecule bound at a $1\ \mu\text{s}$ site is relaxed comparably by its intramolecular proton and protons of the protein. This conclusion was derived previously¹⁷ by a quantitative analysis of the proton profile of cross-linked BSA in highly deuterated solvent. Put another way, Zeeman energy does not diffuse very far in liquids unless it is transported chemically.

2.6 Summary of the Dynamics of Water in Diamagnetic Protein–Water Systems

The picture presented so far, which derives from relaxometry measurements of deuteron and proton $1/T_1$ NMRD profiles of water in a range of protein–water systems of increasing complexity, models water as a slippery hard sphere. Despite the extended hydrogen bonding within the extended liquid, water can rotate substantially and move its own radius in times no longer than about 10 ps. These multiple bonds do not impede the rotational (or translational) motion of a water molecule; this time is 3 ps, not $1\ \mu\text{s}$. The reason for this is that

rotation of a water molecule involves a concerted breaking and reforming of four bonds, which does not impose the energy requirements associated with removing a water molecule from an interfacial protein–water site, akin to evaporating it into the solvent. This is a major point, since the distinction amounts to more than six orders of magnitude difference in the relevant rate processes. (It is also not established theory, but an observation that is part of, and follows from, the larger picture of water mobility in biological systems, as discussed here.)

Macromolecular solutes (and small solutes) influence the molecular dynamics of water molecules only during physical collisions at solute–solvent interfaces. For proteins it was shown that four classes of interaction can be distinguished, corresponding to binding of water molecules to the protein by one, two, three, or four hydrogen bonds. For four bonds, the lifetime τ_M of the complex is about $1\ \mu\text{s}$; the lifetime is proportionately shorter for the other configurations (see Table 1). The relative densities of such sites appear to be similar for most proteins, including the proteins of most tissue, at least near physiological values of pH. The values of $1/T_1$ are very sensitive to the long values of τ_M , a $1\ \mu\text{s}$ site generating an almost a million-fold enhancement of the magnitude of the perturbed water dynamics, making relaxometry relevant to MRI diagnostic radiology.

3 LIPID–WATER INTERACTIONS

Lipids, although minority constituents of tissue, are all important in that they form membranes which control the spatial organization of both macromolecules and small ions within and between cells. The interactions that concern us are interfacial, with the added feature that water can, and does, permeate membranes. The discussion in the earlier sections shows that, to first order, the presence of a plethora of membranes does not restrict the motion of water on a relaxation timescale (with the possible exception of organs designed to filter body fluids, such as kidney). The permeability to water of realistic biological membranes is often greater than in their analogs because of specialized pores that enhance water exchange. Nonetheless, exchange is also rapid in ideal systems, as expected from the generalizations presented above for water in protein and tissue and now extended below to water in lipid.

3.1 Myelin of White Matter

Myelin is the lipid of white matter, the membranes of specialized cells that generate a lipid–cytoplasm–lipid–... 'jelly-roll' of electrical insulation and structural rigidity that surrounds the long axons which connect grey matter with other parts of the brain and beyond. About half the lipid includes a range of (unusual) phospholipids, with the polar and charged groups projecting into the intra- and extracellular spaces. Their contribution to the $1/T_1$ of white matter, as expected from the small contribution to the $1/T_1$ of the polar groups in the hydration layers of protein,²⁶ is too small to be resolved with any certainty in lipid systems³¹ because of their limited solubility. On the other hand, half of the myelin lipid is cholesterol, a multiring alcohol that is highly insoluble in water and which adds to the stability of lipid–water systems by

dissolving in the lipid phase with the alcohol moiety projecting into the aqueous phases. This provides an extensive array of opportunities for interfacial hydrogen bonding. The presence of cholesterol also rigidifies the membrane, making it more like the solid state, and thereby increasing cross relaxation between water and lipid protons.³² Studies of the NMRD profiles of white matter contain a contribution to $1/T_1$ from myelin that can be explained by assuming that each cholesterol has a hydrogen-bonded water with a lifetime of about 200 ps. (This corresponds to a continuous surface about 15 times more effective³¹ at relaxing water than montmorillonite clay.²⁹) From the data on interfacial interactions of water and protein (see Table 1) this suggests a geometry with two hydrogen bonds. The stereochemistry remains to be described, but the picture that emerges—particularly in the larger context—is quite satisfying. As an aside, the foregoing means that the widely known images of the adult brain in T_1 -weighted MRI, in which white matter is much brighter than gray matter, is a map of the intact cholesterol-containing myelin of the white matter.³¹ This relative brightness is not found in unmyelinated white matter of infants and it is altered in white matter disease by mechanisms that have yet to be quantified.

3.2 Permeability of Lipid Bilayer Membranes to Water

The water of myelin is about 15% of the water of white matter, so that unless it mixes with the majority (intra-axonal) water within the appropriate relaxation time (at physiological temperatures), myelin could not contribute to $1/T_1$ as generally measured. On a grander scale, white matter would not appear brighter than gray matter in MRI, since it is myelin that contains the needed relaxation sites. The question is what determines the permeability of lipid bilayers to water?

Here we elaborate the view that there is little that impedes the dynamics of a given water molecule in an extended solvent; water in water or water in lipid? Simply put, the molecular dynamics of water moving through an H_2O environment cannot be much different from water moving through an H_2C environment (the methylene groups that dominate lipid environments). The major difference between water and lipid environments arises from, on average, the four hydrogen bonds that a water molecule makes with its nearest water neighbors and which is absent for water in lipid.

A second difference between a water molecule in water and one in lipid is their different energies; water is highly polar (i.e. has a high dielectric constant), lipids are not. Call it image forces, electrostatics, or something more sophisticated, the extra electrostatic energy of a water molecule within a lipid reduces its probability of being there when it can be elsewhere—in particular when it can be in bulk water in contact with lipid. Thus the partition coefficient of water in water compared with water in lipid can be many orders of magnitude in favor of there being little water in the lipid. However, once there, given that the diffusion of water in lipid must be close in value to the self-diffusion of water, one can readily estimate that, for a water molecule somewhere within a (typical) 15 nm thick lipid membrane, water will escape in less than 50 ns. This view, based on the idea that it is in general very difficult to hold a water molecule chemically or physically, is the essence of the dissolve-and-diffuse theory of membrane permeability, which has been reviewed elsewhere.³³

Although not universally accepted, it is a simple and broadly applicable concept that follows from a larger picture of the dynamics of water in biological and related systems.

It is not simple to measure the permeability of bilipid layers either accurately or rapidly. An NMRD method was reported recently³⁴ which is rapid and accurate for those lipids that can be made to form unilamellar vesicles of relatively uniform size, something that is not too difficult to do in many instances. The technique is to entrain a chelated paramagnetic ion, of known NMRD profile, within the vesicles at a sufficiently high concentration such that $1/T_1$ within the vesicle is comparable to or less than the time it takes for a water molecule to ‘escape’ from the interior of the vesicle by permeation. The details are given elsewhere,³⁴ but typical results are shown in Figure 5. Here the influence of temperature and cholesterol on the permeability of POPC (1-palmitoyl-2-oleoyl-phosphatidylcholine) vesicles is shown for 100 nm diameter vesicles. The paramagnetic ion is Gd(DTPA) (diethylenetriaminepentaacetic acid), the relaxivity of which has been examined in great detail²⁰ given that it is used extensively as a contrast-enhancing agent in MRI. The accuracy or, at least the reproducibility, of the method can be gleaned from Figure 5. Data for one sample can be collected and analyzed in half a day. Interestingly, the escape time is of the order of milliseconds, which is shorter than the deadtime of earlier stopped-flow measurements that claim

Figure 5 P_d , the permeability to water of bilayers of POPC unilamellar vesicles (100 nm diameter) as a function of temperature, for several values of cholesterol content. The vesicles, which occupy a small fraction of the total volume, contained sufficient paramagnetic ions (Gd(DTPA)) to make the $1/T_1$ of water protons within the vesicles comparable to the time required for water to ‘escape’ by permeation. The form of the $1/T_1$ NMRD profiles is then a function of the ratio of these two times, from which the permeability can then be calculated. (Reproduced by permission from S. H. Koenig, Q. F. Ankong, R. D. Brown III; M. Lafleur, M. Spiller, E. Unger, and C. Tilcock, *Magn. Reson. Med.*, 1992, **23**, 275)

to measure permeability by the swelling time of osmotically stressed vesicles.

3.3 Summary of the Dynamics of Water in Lipid–Water Systems

Lipid–water interfaces are quite different from their protein analogs. Unless the lipid contains components that have not only hydrophilic moieties but also, more specifically, OH (and possibly other) groups, and a surface geometry that favors extensive hydrogen bonding, the interfacial collisions are hard sphere collisions with no transient complex formation and little observable effect on $1/T_1$.

There is another major difference between lipid and protein interfaces. Proteins, because of their three-dimensional bonded structure, are not penetrable by water (on the timescales of interest here), whereas lipids have little lateral cohesion and water can readily penetrate, at least sterically. From the vesicle data (Figure 5), which gives an escape lifetime of the order of milliseconds and a transit time of about 50 ns, one can estimate that one encounter in 20 000 of a water molecule at a lipid bilayer interface will be successful in getting the water in. This makes it appropriate to consider these membranes as relatively impermeable. The kinetic factor (20 000) should (intuitively, according to the thinking here) relate directly to the equilibrium solubility of water in the lipid; in fact, it is a number that agrees well with the very low solubility of water in most lipids.³³ Nonetheless, the infrequent penetration of the membrane by water is generally sufficiently frequent to allow water to average out the intra- and extracellular environments of water within a relaxation time, thus making the NMRD profiles of tissue relatively insensitive to specific details of both the anatomical and histological morphologies of tissue, as can be observed.

4 QUANTIFICATION OF THE DYNAMICS OF WATER ON THE MOLECULAR SCALE: RESULTS FROM MAGNETIC SOLUTES

The emphasis above has been on the liquidity of water and how little its qualitative behavior is influenced by the presence of macromolecule–water interfaces and the specifics of the surface chemical composition. However, with the exception of the reference to results for clay²⁹ no quantitative results are presented that give values for the self-diffusion of water at this level (either translational or rotational) or the relative diffusion constants of molecular and macromolecular solute. A set of useful quantitative results can be obtained from the NMRD profiles of water protons in solutions of magnetic solutes. In the very early days of NMR such relaxometry data were used to learn about the structure of solutes,¹⁴ with the assumptions about their influence (or lack thereof) on the solvent being left implicit. Due to the advent of MRI and the wide use of magnetic pharmaceuticals for altering contrast in MRI, enough is now known about the structure of many such solutes and the theory of their relaxivity that their presence can be used to probe the mobility of water in their vicinity. In essence, these particles produce magnetic fields that contribute to the relaxation of water protons out to a distance of about one

solute diameter from the solute surface; this is called ‘outer sphere’ relaxation. In addition, the smaller agents (exemplified by Gd-DTPA) form a complex with a single water molecule coordinated directly to the metal ion which is in rapid exchange with solvent; this is ‘inner sphere’ relaxation.

4.1 Gd(DTPA)

About half of clinical MRI procedures involve magnetic agents, predominantly a commercial preparation of Gd(DTPA). Although this is often referred to as a paramagnetic agent [the magnetic susceptibility of solutions of Gd(DTPA) do exhibit classic Curie-law behavior], from the point of view of a mobile water molecule near a Gd(DTPA) solute molecule the water protons experience a fully magnetized S-state ion, spin of $\frac{7}{2}$, and a magnetic moment of 7 Bohr-magnetons from the parallel spins of the half-filled f shell. Thus, for our purposes, Gd(DTPA) can be considered as one of the smallest ‘ferromagnetic’ solute particles, with the seven spins of each particle permanently parallel.

Admittedly, particularly at low magnetic fields, the spatial orientation of the gadolinium moments fluctuates rapidly, corresponding to an electronic T_1 (τ_{1S}) of about 100 ps. However, this relaxation time, which affects both inner sphere and outer sphere relaxation, is field dependent^{14,20} and, at typical imaging fields, τ_{1S} becomes much longer than the two other correlation times that contribute to the relaxivity of Gd(DTPA). These are τ_R , the reorientation time of the solute due to Brownian motion, which controls inner sphere relaxation and τ_D , a diffusional correlation time comparable to the time required for a water molecule to leave the solute environment, which controls outer sphere relaxation.

Figure 6 shows the measured proton $1/T_1$ NMRD profile of a solution of Gd(DTPA), together with two curves derived from theory (broken lines) for the (comparable) inner and outer sphere contributions to the relaxivity.²⁰ The inner sphere results assume one inner-coordinated water molecule in the usual geometry, with a lifetime of 1 ns, taken from that of the gadolinium aquoion. (Recent work has shown this time to be unexpectedly long,³⁵ about 250 ns, but this has little effect on the present discussion.) The zero field electronic relaxation time τ_{1S0} used is 85 ps, a correlation time τ_V of 20 ps characterizes its field dependence, and τ_R is 80 ps; this generates the inner sphere curve shown in Figure 6. Indeed, at high fields, τ_R is the only adjustable parameter that determines inner sphere relaxivity. For the outer sphere contribution, a τ_D of 41 ps and a (hard sphere) distance of closest approach a of 0.36 nm were used. Similarly, at high fields, the outer sphere contribution depends only (inversely) on a and the relative diffusion constant D of solute and solvent through the relation $\tau_D = a^2/D$. In turn, a must agree with the known crystallographic structure of Gd(DTPA). τ_R also depends on a and the applicability of Stokes’ law at these molecular dimensions. Thus, there is little room to adjust the parameters that determine the relaxation at high fields. The high field data by themselves demand, in essence, that water behaves as a continuum fluid with fixed transport parameters even at solute dimensions, with a hard sphere interaction with the relatively small solute Gd(DTPA) molecules. In addition, since the inner and outer sphere contributions depend differently on field, fitting of the entire profile to theory fixes the relative amount

Figure 6 $1/T_1$ NMRD profile of water protons with solute Gd(DTPA) at 25 °C. The solid curve through the data is the sum of two contributions (broken lines): that of a single water molecule in rapid exchange from the inner coordination sphere of the gadolinium ion, and that of water molecules diffusing in the magnetic field of the gadolinium ion in the outer sphere environment of the chelate complex (see text). (Reproduced by permission from S. H. Koenig and R. D. Brown III, *Prog. NMR Spectrosc.*, 1990, **22**, 487)

of inner and outer sphere contributions, further constraining the values of the system parameters that describe the observed relaxivities. It is a fair estimate that small alterations (of the order of $\pm 30\%$) of the parameters given would make a self-consistent fit of data and theory difficult.

4.2 Gd(DTPA) in Blood

In diagnostic radiology Gd(DTPA) is injected intravenously into the circulation where it mostly remains until excreted through the kidney. Its utility of course involves a balance of contrast enhancement versus toxicity, so that it is a realistic question as to whether NMRD data (Figure 6) can predict the behavior of Gd(DTPA) in clinical applications. Blood, like most tissues, is 20% solid, with one-third of its water in the dominant red cells. These contain the majority of blood protein (hemoglobin), although the extracellular space (plasma) contains an additional 30% of the total protein. The questions associated with Gd(DTPA) in blood are whether the agent attaches to, or enters, the cells and whether it binds to protein. Binding of small paramagnetic agents to macromolecules, which increases τ_R dramatically, can alter the NMRD profiles in the MRI field range in a particularly favorable way in a manner that is understood but not predictable.^{15,20} From NMRD profiles of blood with and without added Gd(DTPA), and of the plasma that remains after the cells settle, it is readily demonstrated³⁶ that, from the water molecule's viewpoint, the partitioning of the blood by the cell membranes is irrelevant to relaxation, as the presence of macromolecules is to the relaxivity contribution of Gd(DTPA). All constituents—extracellular plasma protein, intracellular hemoglobin, and Gd(DTPA)—contribute independently to the

NMRD profile of blood, with appropriate consideration given to excluded volume effects.

4.3 Superparamagnetic Particulates

Virus-size particles of iron oxide, predominantly magnetite, are becoming of increasing interest to the MRI community. Unlike smaller agents, these are removed from the circulation and deposited elsewhere in the body, apparently in ways that may prove useful for imaging liver, spleen, and marrow. These small 'nanoparticles,' typically in the range 5–10 nm diameter,³⁷ are generally protected from body fluids by attachments of polymeric sugars or starches designed to impede access of water as little as possible to the outer sphere environment of the iron oxide cores. They are termed 'superparamagnetic', a word that is ambiguous in that it can be properly applied to individual particles as well as to an ensemble of such particles in solution. In the latter case it means, as for Gd(DTPA), that the magnetic susceptibility of a solution obeys Curie's law, but now with a 'super' response. This is because the magnetic dipolar moment of each solute particle is very large and because the susceptibility of a solution containing a fixed total number of magnetic ions increases quadratically with the number of ions in each solute particle and only linearly in the total number of particles. Since a magnetite nanoparticle may contain about 5000 magnetite molecules,³⁸ susceptibility is enhanced by a factor of about 5000 over that of a solution of individual magnetite molecules. Ironically, the superparamagnetic aspects of the individual particles do not influence the behavior at imaging fields.²⁰

Again, relaxometry studies of these particles, of which there are few—particularly on particles that are well-characterized chemically and magnetically—yield information on both solute and solvent. Here, outer sphere relaxation dominates, but the range is 10 times greater than for Gd(DTPA), which makes τ_D (which is proportional to the square of this range) very long and the intrinsic relaxivity of these particles very large. This is further enhanced because the relaxivity is also linearly proportional to the 'supersusceptibility' of the solute particles. Thus small total amounts of agent, far less on a molar basis of magnetic ion than for typical gadolinium chelate complexes, may prove adequate for diagnostic MRI. To this must be added that iron is an endogenous ion and questions of relative toxicity may favor iron over gadolinium. In any event, the increasing interest in such agents is making more relaxation data available and providing more knowledge of the behavior of water on a 10 nm scale. Again, 'water is water'. Initial results for particles with relatively narrow size distributions, measured by microscopy of one sort or another (X-ray, electron transmission, etc.) give contributions to $1/T_1$ at imaging fields¹⁷ consistent with their size, using macroscopic values for the self-diffusion of water in microscopic environments.

4.4 Summary of Findings for Magnetic Solutes

There is a large body of literature on the influence of magnetic solutes, including metalloproteins, that has been discussed elsewhere.¹⁵ The points considered here relate to the reality that the theory of relaxation of solvent protons

by magnetic solute has been improved remarkably within the past decade,³⁹ in part spurred by advances in clinical MRI and its incorporation of magnetic pharmaceuticals into its routine practice. Particularly as regards outer sphere relaxation in solutions of nanoparticles and larger particles (including paramagnetic red cells⁴⁰), theory and data are in excellent agreement (even though the computations may be difficult). This agreement assumes the fluidity and mobility of water, often through organic binders and flagellate attachments³⁷ to the iron oxide cores of the nanoparticles.

There is one point that ought to be made for completeness, which relates to inhibition of inner sphere relaxation by protein-bound paramagnetic ions by the inhibition of protein function. Examples of this would be binding of sulfonamides to cobalt-substituted carbonic anhydrase and the reduction of cupric to cuprous ions in superoxide dismutase. The result is an NMRD profile like that of the diamagnetic protein, i.e., either demetalated or substituted with a diamagnetic metal ion. One might ask, on the basis of the extended diffusion of magnetization within immobilized protein considered in the sections above, whether in metalloproteins there is any contribution to the water proton relaxation by the magnetization diffusing through the protein to get around to the back of a paramagnetic ion for which water has been excluded by complex formation. The answer is that for mobile proteins no such effect has ever been reported, and for immobile proteins, that no pertinent data are available.

5 WATER AS A VISCOUS VACUUM

Important as the dynamics of water are for the proper functioning of biological systems, it is the behavior of the macromolecular solute, mainly protein, that underlies the functioning of these systems. Moreover, living systems typically contain about 20 wt % solids, mostly protein, a concentration far greater than the values of <1% that typify physico-chemical studies of protein in solution. There has been little emphasis on bridging this gap; understanding the behavior of protein at high concentration is often regarded as a hopeless activity. However, from our understanding of the dynamics of water in these systems, discussion of protein–protein interactions in solution at high concentration can be made simple. Several examples follow.

5.1 Rotational Relaxation of Solute Protein at High Concentration

For example, how free to rotate is the hemoglobin of red cells? The answer is known:¹⁵ it is as free to rotate as in an infinite solution of hemoglobin at the same concentration, which is about 10 times slower than in the dilute limit. Is this reasonable: and what are the underlying physics? First, we remark that almost all soluble (globular) proteins have the same partial specific volume ($0.73 \text{ cm}^3 \text{ g}^{-1}$, with the exception of eye-lens protein, for reasons of lens transparency^{25,41}), so that solute protein molecules can be regarded as relatively incompressible microsolids. As shown by Stokes in the middle of the last century, the rotational relaxation time of a sphere of radius r in an infinite viscous medium is proportional to

its (macroscopic) viscosity η_0 . Stokes also showed that if the sphere is at the center of a stationary larger sphere of radius R , its rotational relaxation time will increase as if the viscosity of the infinite medium were given by

$$\eta = \frac{\eta_0}{1 - [r/(R - r)]^3} \quad (2)$$

The increase in apparent viscosity is a geometric factor that is solely a function of the volume fraction occupied by the smaller sphere, i.e. the scale of the spheres is not germane (and of course should not be for a particle in a continuum fluid). For the protein–protein problem, let the outer sphere be an imaginary one defined as the largest sphere that excludes, on average, all protein neighbors of a given protein. If r is taken as the protein radius, and the radius of the imaginary sphere is taken as R in the Stokes example, then this simple model²⁶ affords an excellent description of the rotational mobility of hemoglobin as a function of protein concentration, up to the physiological concentrations in the red cell. Thus the interaction of proteins in solution is determined, in the main, by classical hydrodynamics, provided that there is no appreciable equilibrium association of solute.

5.2 Thermodynamics in a Viscous Vacuum

When considering the thermodynamics of an aqueous solution of protein at high concentration from the chemical viewpoint, it is usually handled as a two component system in equilibrium, with free energies being equal for the two components and for any other oligomeric forms in equilibrium with the monomer. From this viewpoint, it is difficult to address questions of, for example, osmotic pressure and possible phase separation. On the other hand, if one accepts the argument that the dynamics of water are little influenced by solute protein, then—realizing that equilibrium results derived from statistical mechanics of interacting particles are independent of the laws of motion of the particles—it becomes a powerful simplification to treat solute protein as a single system of interacting particles. The water may be considered as a vacuum in which Newton's laws are replaced by the response to a force typical of a viscous medium, and then ignored. The solute is then a hard sphere gas of identically charged particles that are weakly repulsive because of the high dielectric constant of water. Two extremely important results follow immediately, both of importance to the eye lens, in which the proteins reach uniquely high concentrations. One result is that the osmotic pressure of these proteins should be given by the results for hard spheres, as they are.⁴¹ The second result is that, since a (three-dimensional) hard sphere gas with a repulsive interaction cannot have a first-order phase transition, the phase separation seen in one such protein, γ H-crystallin, must be due to oligomerization and the creation of a multicomponent solute system.⁴²

6 CONCLUDING REMARKS

Water in biological systems is in no sense innocuous. The polarity of its molecules (otherwise identical to neon) leads to a high dielectric constant, and thus water dissolves

and ionizes many salts. It also leads to extensive hydrogen bonding and the density minimum that keeps the oceans from freezing permanently. But once these effects are accounted for, which is done here by a 'renormalization' of attitude, then the molecular dynamic properties of water molecules can generally be ignored. Indeed, in order to use water in specialized ways in chemical reactions in biological systems, Nature has had to invent metalloproteins—with emphasis on the transition metals. In these compounds the water molecules can be maintained in desirable stereochemical orientations for times sufficient to allow enzymatic reactions to proceed, molecule by molecule. But this is another subject.

1 INTRODUCTION

Proteins and nucleic acids contain many polar hydrogens that are in continual exchange with the hydrogens of a solvent. These hydrogens are distributed throughout the main chains and side chains of proteins and the nucleotides of nucleic acids. The different hydrogens in a protein molecule exchange over a vast range of rates, 10 orders of magnitude or more wide; the spread in nucleic acid rates is considerably smaller. These atoms, placed at many dozens, even hundreds, of positions throughout every macromolecule, emit a continual stream of information, in a nonperturbing way, in the coded language of hydrogen exchange (HX) rate, concerning structure, structure change, dynamics, and energetics. This is just the kind of information we need to work out the fundamental principles of structural stabilization and function. We have but to receive and decode the information in these terms.

Multidimensional NMR methods (See *Multidimensional Spectroscopy: Concepts*.) now make it possible to resolve the signals from each exchanging hydrogen, identify its parent proton in the molecule, and measure its HX rate. Fast exchanging hydrogens can be followed by methods based on magnetization transfer and lineshape analysis. Slower hydrogens can be measured in isotopic ^1H – ^2H exchange experiments. The literature details a variety of NMR methods for HX measurement, using both 1D and multidimensional approaches. NMR-detected HX behavior has been discussed previously.^{1,2}

The present article briefly presents the conceptual and technical information necessary for the design and execution of protein and nucleic acid HX experiments and summarizes some important recent applications. HX coupled with NMR detection accesses a whole new dimension of dynamic behavior in proteins and nucleic acids and allows a direct measurement of their important thermodynamic stability parameters. Further, HX labeling experiments can provide fairly detailed structural information on protein forms that defy the usual NMR and even X-ray methodologies.

2 NOMENCLATURE

Use of the term ‘proton exchange’ reaches back to the early NMR literature in which protons played the predominant role. One now studies in various ways the exchange of protons, deuterons, and tritons. Thus the generic term ‘hydrogen exchange’ should be preferred, and is used here. Similarly, the use of the term ‘amide’, for the peptide group of proteins, derives from its chemical shift position in the amide region. Proteins have three kinds of amides, the primary amide side chains of asparagine and glutamine, the secondary amide or peptide group, and the tertiary amide of prolyl residues. One should specify the peptide group by its proper name.

3 HX CHEMISTRY

The HX behavior of protein and nucleic acid molecules can provide direct information on their structural dynamics and functional interactions. These effects are superimposed on the underlying HX chemistry of the exchanging groups studied. Thus, knowledge of basic HX chemistry is essential for the interpretation of HX results.

HX between water and solute molecules proceeds by way of distinct chemical reactions that involve as catalysts H_3O^+ , OH^- , and general acids and bases, including H_2O itself. The primary steps in a hydrogen exchange sequence involve proton transfer reactions [equation (1)].

For unstructured polymers in free solution, diffusion-limited collision and hydrogen bond formation between a proton donor (AH) acting as an acid and a base acceptor (B) occur with the second-order rate constant, $k_D \sim 10^{10} \text{ M}^{-1} \text{ s}^{-1}$. Within the hydrogen-bonded encounter complex thus formed, hydrogen redistribution occurs rapidly, by tunneling, and reaches an equilibrium given by $K_c = 10^{\Delta pK}$, where $\Delta pK = pK_B - pK_A$. Presently the complex dissociates, either to the left of equation (1) in a wasted collision, or to the right in a fruitful one. The overall hydrogen transfer rate is given by the collisional rate times the success rate [equation (2)]

$$k_{tr} = k_D(10^{\Delta pK} / (1 + 10^{\Delta pK})) = k_{ch} \quad (2)$$

The rate-limiting chemical step in any HX reaction (k_{ch}) is always such a transfer sequence. When transfer is energetically downhill (stronger acid to weaker acid), $\Delta pK > 0$, the success fraction is close to unity, and HX goes at k_D . When transfer is energetically uphill ($\Delta pK < 0$), exchange can be much slower, with $k_{ch} \approx k_D 10^{\Delta pK}$. For example, the ring nitrogen-bonded protons (NHs) of nucleotides and most protein polar side chains, with $pK < 15$, are removed by OH^- at $k_{ch} \sim 10^{10} \text{ M}^{-1} \text{ s}^{-1}$. In contrast, removal of a peptide group NH by OH^- , a transfer from donor $pK \sim 18.5$ to acceptor $pK 15.7$, is slower by ~ 1000 -fold. Similar considerations apply to catalysis by H^+ and by general acids and bases. As a result, the polar hydrogens of protein side chains exchange rapidly, and therefore are relatively useless for structural studies, and also are hard to assign. Peptide group NH exchange is more accessible, being intrinsically slower and not catalyzable by general acids and bases. The tryptophan indole NH is also

usefully slow. In nucleic acids, the ring NHs, with $pK \sim 10$, can be catalyzed effectively by general bases as well as by OH^- , while the strongly basic exocyclic NH_2 hydrogens cannot. Carbon hydrogens are exceedingly slow; they do not readily form hydrogen bonds on collision, and do not transfer easily due to their high effective pK .

Most protein HX studies center on the well distributed and slowly exchanging peptide group NH. Figure 1 shows the pD dependence of its exchange, reflecting simple catalysis by OH^- above $\sim \text{pH } 3$ (in polypeptides) and by H^+ at lower pD. The figure shows that HX of the freely exposed NH can be sterically blocked by neighboring bulky side chains [Figure 1(a)] and can also be modified by inductive effects [Figure 1(b)] due to neighboring polar side chains.

Figure 1 HX of free peptide NH in small molecule models. (a) Steric blocking effects and (b) inductive effects of neighboring amino acid side chains are illustrated. Polypeptides show pH minima between pH 2.5 to pH 3. L, left; R, right. (Reproduced by permission of John Wiley and Sons, Inc. from Bai et al.)³

These effects along with other influences such as temperature, sequence, and isotope effects have been calibrated for all the naturally occurring amino acids.^{3,4} Figure 2 shows a similar representation for some nucleotide bases. The odd behavior of the adenine NH_2 hydrogens includes catalysis by OH^- at high pH, and by H^+ at low pH. At intermediate pH, HX

Figure 2 The pH dependence of HX for some nucleotide NHs [uracil (Ur) and AMP]. (Reproduced by permission of Cambridge University Press from Englander and Kallenbach)⁶

proceeds by a reaction that involves an initial protonation at the N-1 position (normally buried in the double helix) followed by a deprotonation either by OH^- or by a general base at sufficiently high concentration. The $\text{H}^+ \times \text{OH}^-$ reaction produces the pH-independent behavior seen in the figure.

When these groups are involved in structured macromolecules, the basic chemical exchange rate can be decreased by large factors. One commonly expresses the structural slowing or protection factor as $P = k_{\text{rc}}/k_{\text{ex}}$, where k_{rc} [equation (2)] is the computed rate for the group in a structureless random coil, dependent on the principles^{5,6} just discussed and calculated from calibrations using model molecules (in peptides^{5,6} and nucleotide HX chemistry).^{7,8}

4 HX RATE AND STRUCTURAL DYNAMICS

HX slowing by folded structure is due to a physical blocking of the chemical steps just described. Structurally slowed hydrogens are, in the great majority of cases but not always, involved in hydrogen bonding. One assumes that exchange cannot occur unless the blocking structure is removed. Under native conditions this requires a transient opening reaction that has been modeled by various authors as a breaking of individual hydrogen bonds,⁹ a local cooperative unfolding,⁶ or even a gross whole molecule transient unfolding.¹⁰ Over the years other possible mechanisms, based on various kinds of catalyst and solvent penetrational processes, have been suggested.^{6,10}

Opening dependent exchange can be schematically represented as in equation (3):

In the steady state, this reaction sequence produces HX rates given by equation (4):

$$k_{\text{ex}} = k_{\text{op}}k_{\text{rc}}/(k_{\text{op}} + k_{\text{cl}} + k_{\text{rc}}) \quad (4)$$

At the so-called EX1 limit,⁹ where $k_{\text{cl}} \ll k_{\text{rc}}$, this leads to the HX rate in equation (5), which has hardly ever been seen:

$$k_{\text{ex}} = k_{\text{op}} \quad (5)$$

Equation (6) gives the HX rate at the usually observed EX2 limit, where $k_{\text{cl}} \gg k_{\text{rc}}$:

$$k_{\text{ex}} = (k_{\text{op}}/k_{\text{cl}})k_{\text{rc}} = K_{\text{op}}k_{\text{rc}} \quad (6)$$

These equations assume that structure is stable, so that $K_{\text{op}} \ll 1$. K_{op} is then essentially equal to the fraction of time the restraining structure is open [fraction open = $K_{\text{op}}/(K_{\text{op}} + 1)$]. Since values for k_{rc} , the HX rate for NHs in a random chain polypeptide, are known,^{3,4} the measurement of k_{ex} leads to K_{op} [equation (6)], and thus to the free energy for the underlying structural opening reactions, according to equation (7):

$$\Delta G_{\text{HX}} = -RT \ln K_{\text{op}} = -RT \ln(k_{\text{ex}}/k_{\text{rc}}) \quad (7)$$

Measurement of the dependence on temperature can then provide ΔH and ΔS of the dynamic opening reaction. Effects of mutations, functional state, etc., on stability can similarly be studied.

NMR methods have been developed that can measure a range of dynamic structural behavior, due to dipolar relaxation in solution (<1 ns), quadrupolar relaxation in solids (<1 μs), and slower chemical shift averaging (~ 1 ms) and saturation transfer (~ 1 s) effects. The equations just described extend this capability to an entirely different class of structural events, selected by the fact that they can allow solvent catalyzed HX chemistry to proceed. The timescale of the structural events measured by HX has elicited some confusion. The underlying structural events themselves occur on a fast timescale, with k_{cl} rates between seconds and nanoseconds. Opening events are of course slower than closing when the structure is stable ($k_{\text{cl}} > k_{\text{op}}$). The HX timescale itself is far longer, in the general range between milliseconds and years. As described before, the HX rate depends on solution conditions (k_{rc} ; Figure 1), which can be set at the convenience of the experimenter, and on the equilibrium structural parameter, K_{op} , which can vary from close to unity for the smallest fluctuations down to perhaps 10^{-10} for global protein unfolding reactions. To measure the structural timescale at work, in any case, one must access EX1 behavior [equation (5)]. This has hardly been possible for proteins, specifically because k_{cl} is so fast, but has been accomplished for nucleic acids.^{7,8}

5 APPLICATIONS: MACROMOLECULAR DYNAMICS

5.1 Protein Structural Thermodynamics

Protein molecules spend a small fraction of the time cycling through their global unfolding transition, even under normal solution conditions, determined by their free energy for unfolding and the Boltzmann distribution. Some of the slowest protein hydrogens exchange by way of this transiently open state. Therefore, it is possible to obtain global thermodynamic parameters by HX measurements far below the melting transition [equation (7)].

Figure 3 shows simulated data for HX measurements of some of the slowest exchanging NHs in a protein and for some faster ones, calculated in terms of the ΔG of the operative unfolding reaction. At present one must study protein stability by obtaining data through the melting transition, about $\Delta G = 0$. From such measurements one hopes to obtain thermodynamic parameters, and then to extrapolate into the region of more normal conditions. HX analyzed by 1D NMR can allow the direct determination of the operative parameters at much lower temperatures or much lower denaturant concentration, under conditions where proteins are stable.¹¹ Similarly, hydrogens that exchange by way of more limited openings can reveal the stability parameters of these fluctuations.

Since the slowest peptide NHs in a protein can often be resolved and their H-D exchange directly measured in D_2O by simple 1D NMR spectroscopy, this approach has considerable promise for protein stability studies.

5.2 Nucleic Acid Structural Dynamics

Nucleotides have two kinds of exchangeable NHs, the exocyclic amino NH_2 hydrogens and the endocyclic imino ring

Figure 3 Simulated behavior for the HX of some protein NHs, calculated in terms of the ΔG of the operative unfolding reaction. The slowest NHs (curves 1) exchange through the global unfolding reaction, and the faster ones (curves 2–5) by way of more local unfolding reactions. (Reproduced by permission of John Wiley and Sons, Inc. from Bai et al.)¹¹

NHs (see Figure 2). In the double helix, A–U and A–T base pairs trap two of their three NHs in hydrogen bonding. G–C pairs trap three of their five NHs. The other NH₂ hydrogens hydrogen bond out to water.

HX results found are contrary to all expectations. All the hydrogens in a Watson–Crick base pair exchange slowly, three for each A–T or A–U pair and five for each G–C. The most deeply buried hydrogen, the hydrogen bonded ring NH, is the fastest to exchange, while both hydrogens of a given NH₂ group, the one that is internally hydrogen bonded and the one

that is exposed and hydrogen bonded to solvent, exchange at the same rate. All of this surprising behavior is due to a simple fact. In the double helix, nucleotide HX occurs from a transient base pair open form. Thus the relative rates of the different NHs are determined not by their condition in the native structure but by their chemistry in the solvent exposed state, described in a previous section. These basic ground rules were worked out in the laboratories of Englander and Kallenbach by use of tritium exchange methods and by H–D exchange measured by absorption spectroscopy, and have been reviewed by them.⁶

Since polynucleotide HX generally progresses on a timescale of minutes, NMR analysis is limited to 1D methods. Unfortunately, the amino NH₂ resonances overlap the aromatic CHs, and have been difficult to study. Therefore, NMR applications have generally focused on the imino NHs of G, T, and U, which resonate in an otherwise empty high-frequency (down-field) region at 12–15 ppm (see *Nucleic Acids: Chemical Shifts*). Their HX behavior has been measured mainly by line broadening in a ¹H–¹H exchange mode, using water suppression as described by Gueron (see *Water Signal Suppression in NMR of Biomolecules*). Spectral overlap limits the size of oligonucleotides that can be studied.

The earlier non-NMR studies developed the use of catalyzed exchange and the discrimination between EX1 and EX2 behavior based on equations (5) to (7), and concluded that base pair opening equilibria were surprisingly high, with K_{op} up to 0.01, and that opening rates, k_{op} , were in the range of 1 s⁻¹. Gueron and his colleagues, using similar approaches together with 1D NMR methods, have found results that point to faster base pair opening ($k_{op} \sim 10^2$ s⁻¹) and closing ($k_{cl} \sim 10^7$ s⁻¹) rates and correspondingly lower equilibrium opening constants.⁸

These approaches can potentially be brought to bear on a whole range of challenging issues concerning nucleic acid structure, dynamics, interactions, and function.⁸

6 APPLICATIONS: HX LABELING

The application of HX methods to protein problems gains special power when used in the labeling mode. Here H–D exchange can be done under conditions most suitable for the protein behavior to be studied. An H–D exchange pattern that depends on the behavior being measured becomes imprinted on the protein. Conditions can then be reset to make HX slow, and samples can be handled to optimize for NMR analysis.

6.1 Binding Regions in Protein Complexes

Recent experiments with protein complexes too large to study directly by NMR methods illustrate the ability of HX labeling methods to extend the scope of NMR structural investigations. If one of the proteins in the complex is sufficiently small to allow resolution of its individual peptide NHs, the interaction surface of that protein can be delineated in an HX footprinting experiment.

In these experiments, the complex is formed, and placed into D₂O under any conditions one may wish to study. H–D exchange proceeds. NHs not involved in the complex interface

generally exchange at the same rate as when free, although interesting exceptions not yet explained have been seen. NHs in the interface are slowed by varying amounts, depending on the interesting details of the interaction and the chemical and physical principles described before. Samples are taken in time and placed under slow HX conditions (lower pH and temperature). The complex is separated, and a 2D NMR spectrum of the protein to be analyzed is recorded to measure the remaining amplitude of a large number of exchangeable NH resonances. The timed samples trace out the HX kinetics of the various NHs. Comparison with similar data for the noncomplexed protein can then directly indicate which parts of the protein are involved in the binding interface and which are not, essentially to an amino acid resolved level, and can provide other details of the dynamics and thermodynamics of the interaction. The few studies so far available have dealt with some protein–monoclonal antibody complexes, an enzyme–inhibitor complex, and an electron transfer complex. In principle, many kinds of large-molecule interactions might be studied in this way.

6.2 Structure in Floppy Equilibrium Intermediates

Similar HX labeling methods can be used to obtain structural information on protein forms that resist study by the usual X-ray and NMR approaches. One such form is the so called molten globule, which most often shows exceedingly limited chemical shift resolution due to rapid conformational averaging. These forms are produced by mildly destabilizing conditions such as moderately low pH.

The molten globule forms of a few proteins have now been studied by HX labeling detected by 2D NMR. In these experiments, the disordered protein is incubated in D₂O for increasing times. Each peptide NH exchanges at a rate determined by the fact of its involvement in H-bonded structure and by the relative stability of its local structure against the dynamic opening reactions that determine HX rate [equation (6)]. Samples taken in time are returned to native conditions where the H–D pattern, produced during the HX incubation, is essentially frozen. A 2D NMR spectrum is then recorded on the native protein, where one can resolve and identify the various peptide NHs. A series of such spectra on timed samples reveal the HX rates of the various NHs. The results show directly what parts of the protein were involved in structure in the molten globule state and give semiquantitative information on the stability of the different structured segments.

6.3 Structure in Transient Folding Intermediates

The most striking example of the power of HX NMR labeling is provided by its ability to provide structural information on protein forms that exist only transiently, for less than 1 s. The HX pulse labeling experiment is designed to label a protein by H–D exchange during refolding in a structure-sensitive way on a millisecond timescale. Subsequent NMR analysis of the native protein can then provide information on the time dependence of hydrogen bond formation at many defined positions in the protein.

In these experiments, the protein is initially unfolded, for example with a concentrated denaturant such as guanidinium

chloride (GdmCl) in D₂O, so that all the NHs exist as NDs. At time zero of a kinetic experiment, the solution is rapidly diluted into GdmCl-free H₂O under conditions where HX is relatively slow (e.g. pH 6 and 10 °C, where the HX half-time is seconds (Figure 1)). The protein begins to refold. Deuteron to proton exchange under these conditions is relatively slow and does not yet occur. At some time during the refolding process, the solution is subjected to a brief, high pH pulse in a second mixing step in order to label NH sites that are still exposed. For example, at pH 10 and 10 °C, peptide NDs in parts of the protein that are still unfolded will exchange to NHs in ~1 ms, while NDs that have already formed hydrogen-bonded structures will be protected from exchange. The high pH pulse is maintained for a few milliseconds while deuteron to proton exchange occurs. Then a third mix drops the pH to perhaps 5, halting all further exchange. The proteins complete their run to the native form. The H–D exchange pattern, imprinted on the partially folded intermediate, is now frozen into the native protein and can be read by a 2D ¹H spectrum to determine the degree of proton labeling at many positions all through the protein. A series of such experiments, with the labeling pulse imposed after different times of refolding, can then show the time-course for formation of the various hydrogen-bonded sites in the protein, and thus provide direct structural information on the folding pathway. In practice, of course, one can only detect the particular folding intermediates that happen to achieve high occupancy.

The HX pulse labeling experiment has been described in some detail by Englander and Mayne.¹²

1 INTRODUCTION

^{17}O is the least utilized of the NMR active nuclei commonly found in biological systems. While oxygen atoms play an important role in the hydrogen bonding, electrostatics, and hydration of biomolecules, the very low natural abundance (0.037%) and quadrupolar nature ($I = \frac{5}{2}$) of ^{17}O nuclei have hindered the development of ^{17}O NMR as compared with ^1H , ^{13}C , ^{15}N , and ^{31}P NMR in biological systems. Over the last decade, however, the availability of both ^{17}O enriched materials and ever higher field FT NMR spectrometers have led to the utilization of ^{17}O nuclei as probes of biomolecular structure and function, some 40 years after the nucleus was first observed.¹

It is the intention of this article to review the characteristic parameters governing the use of ^{17}O NMR in, and how the behavior of ^{17}O nuclear spin magnetization has been applied to, biological systems. The effects of ^{17}O quadrupolar relaxation on ^{31}P magnetization are also important, but are beyond the scope of this review.

2 ^{17}O NMR PARAMETERS

The detailed quantum chemical description of sites in biologically relevant molecules is, in general, extremely complex. The task is greatly simplified in NMR by modeling nuclear spin interactions as independent of the rest of the system, with time-dependent interactions between spins and the bulk (or lattice) being termed ‘relaxation’. This, and other considerations, allows for the simplification of the ^{17}O NMR of biomolecules to the study of ^{17}O chemical shielding, ^{17}O relaxation (resulting from couplings between the nuclear quadrupole and its local environment), and ^{17}O quadrupole couplings.

The chemical shielding of a nucleus is a function of the electronic structure near the nucleus. ^{17}O nuclei are particularly sensitive to differences in chemical environment;

for example, the two distinct oxygen sites in ozone are separated by 566 ppm.² Differences in chemical shift between sites in a molecule can be used to determine molecular structures, as well as to study dynamical processes in these structures, such as conformational changes, substrate binding, and hydrogen bonding. The ^{17}O chemical shift is commonly referenced to H_2^{17}O in biological NMR studies.

All nuclei with $I > \frac{1}{2}$ have a nuclear quadrupole moment eQ . The interaction of eQ with an electric field gradient eq is quite strong, typically dominating the NMR spectrum of a quadrupolar nucleus. For most biomolecules, the interaction between the eQ of ^{17}O and eq is modulated by rotational motion, either molecular tumbling or internal rotations, making it an efficient relaxation mechanism. In the extreme narrowing limit (very fast motions on the NMR timescale), the nuclear quadrupole relaxation rate essentially determines the resonance linewidth L which can be expressed as

$$L \approx (12\pi/125)(1 + \eta^2/3)\chi^2\tau_r \quad (1)$$

where $\chi = e^2qQ/h$ is the nuclear quadrupole coupling constant, η is the asymmetry parameter of the electric field gradient tensor, and τ_r is the rotational correlation time.³ ^{17}O linewidths are therefore proportional to the square of the electric field gradient at the nucleus, and are generally inversely proportional to the molecular correlation time. This limits the applicability of ^{17}O NMR either to relatively small molecules or to sites in molecules where χ is much less than typically found for ^{17}O nuclei (about 10 MHz, see Kintzinger⁴). Within this limitation, ^{17}O relaxation can be used to measure differences in χ and τ_r for either two sites in the same molecule, or the same site under different conditions. For slow molecular motions ($\tau_r \gg 1/\nu_L$) relaxation is a weighted sum of three exponentials, resulting in deviations from Lorentzian lineshapes, and such effects have been observed experimentally for C^{17}O bound to heme proteins, where χ values are very small (about 1–2 MHz).⁵

3 BIOPHOSPHATES

Biophosphates are involved in many biological processes, such as energy transport and utilization, information storage and retrieval, and membrane structure and transport. Examples of such compounds are adenosine diphosphate (ADP), adenosine triphosphate (ATP), DNA, RNA, and phospholipids.

Tsai et al.⁶ have demonstrated that bridging and phosphoryl ^{17}O resonances in biophosphates can be assigned from their relative linewidths, due to differences in χ between the various sites. Linewidths are all relatively broad, and several groups have demonstrated improved spectral resolution upon sample heating,^{7–11} which decreases τ_r and thereby the ^{17}O linewidths, allowing for more accurate determination of ^{17}O chemical shifts and spin–spin coupling constants, $J(^{31}\text{P}, ^{17}\text{O})$. Gerotheranassis and Sheppard¹¹ also demonstrated the utility of using ^{17}O depleted water to minimize the background H_2^{17}O solvent peak, which in aqueous samples frequently overwhelms the resonance from even an ^{17}O enriched sample.

The pH dependence of the ^{17}O chemical shift has been determined for phosphoryl oxygen atoms in several phosphates, including adenosine monophosphate (AMP), ADP, and

ATP,^{9,10} demonstrating the effect of protonation upon the phosphoryl ¹⁷O chemical shift.

The binding of several diamagnetic ions to ATP has been studied using ¹⁷O relaxation rates.^{12,13} The phosphoryl ¹⁷O linewidth increases markedly upon ion binding, indicating the coordination sites for Mg(II), Co(III), Sc(III), La(III), and Lu(III) in M · ATP_n complexes.

The hydrogen bonding of uridine derivatives has been studied using ¹⁷O NMR.¹⁴ Equilibrium constants and interaction enthalpies of water–uridine hydrogen bond complexes were determined by observing changes in ¹⁷O chemical shift as a function of water concentration, in acetonitrile.

¹⁷O spectra of hemiacetal and aldehydic abasic sites in DNA of importance in DNA damage and repair have been studied,¹⁵ demonstrating the ability to observe approximately 10 μM aldehyde signals in the presence of approximately 20 M solvent ¹⁷O.

4 AMINO ACIDS AND POLYPEPTIDES

The tertiary structures of polypeptides and proteins in aqueous solution are strongly influenced by hydrogen bonding, both within the solute molecule and with the solvent, and ¹⁷O NMR has been used to gain insights into these interactions.

The effects of proton exchange between peptide termini and water on ¹⁷O chemical shifts have been used to probe the electronic structures of amino acids,^{11,16} dipeptides,^{17,18} and peptide carboxamides.¹⁹ The ¹⁷O chemical shift has also been used to monitor the presence of hydrogen bonding in peptide models,²⁰ dipeptides,¹⁸ peptide carboxamide,¹⁹ acylprolines (model β- and γ-turns),^{21–23} and small polypeptides.²⁴

The hydration and aggregation of peptides has been studied using ¹⁷O relaxation measurements. ¹⁷O linewidths of amino acids,^{16,25} dipeptides,¹⁸ peptide carboxamides,¹⁹ and small polypeptides²⁴ have been determined in various solvents, locating hydration sites at carboxylate and carbonyl oxygen atoms, in addition to providing a method of monitoring peptide aggregation. In addition, a ¹⁷O relaxation study of ATP binding to adenylate kinase²⁶ has been reported, demonstrating the feasibility of studying enzyme–substrate interactions via ¹⁷O NMR, providing the ligand is not rigidly held.

¹⁷O chemical shifts have also been found to be torsion-angle dependent in aryl carboxylic esters, acids, and amides,²⁷ and ¹⁷O NMR promises to be a powerful technique for elucidating the structures of membrane peptides and proteins, using oriented samples.

5 CO AND O₂ IN HEMOPROTEINS

The nature of Fe–O₂ and Fe–CO bonding in heme proteins and model compounds has been studied using ¹⁷O NMR. ¹⁷O resonance frequencies and linewidths have been measured for O₂ bound to Vaska's compound,²⁸ O₂ bound to picket-fence and basket-handle porphyrin model compounds,^{29–31} CO bound to peroxidases,³² as well as other hemoproteins,^{5,33} and O₂ bound to hemoproteins in the solid state.³¹ Results were found to be in general agreement with Pauling's ideas of end-on bonding, with additional electrostatic field effects being proposed to take into account the chemical shift variation seen

from protein to protein.³⁴ In Fe–O₂ systems, the chemical shift difference between the two oxygen nuclei has been found to be about 600 ppm,^{29–31} comparable to that found in ozone, consistent with previous analogies between FeO₂ bonding and that found in O₃.

6 SUMMARY AND PROSPECTS

Given the central importance of oxygen in biochemical systems (lipids, proteins, nucleic acids and carbohydrates), there have been remarkably few studies of ¹⁷O NMR chemical shifts, and even fewer studies aimed at detailed, quantum chemical analyses of chemical shifts and quadrupolar couplings. ¹⁷O NMR in biochemistry is therefore still in its infancy. However, with the advent of 750 MHz spectrometers, the current development of 900–1000 MHz machines, as well as recent development in quantum chemical applications to macromolecules,³⁵ ¹⁷O NMR can be expected to benefit enormously over the next few years. Thus, ¹⁷O chemical shifts and quadrupole couplings can be exploited to analyze, for example, lipid headgroup and backbone orientations in membranes, sterol orientations and interactions, peptide/protein structures in condensed phases, carbohydrate conformations and interactions, as well as small DNA structures. For ¹⁷O, only relatively low resolution magnets are required, thus the sensitivity gains possible with very high-field operation can be readily exploited. Indeed, most ¹⁷O NMR studies of biochemical systems reported to date could have been obtained at about 1 ppm resolution only. With recent improvements in computer price/performance ratios, and much more efficient algorithms, theoretical analyses of ¹⁷O shifts and χ values are also to be expected. Thus, ¹⁷O NMR in biochemistry undoubtedly has an extremely bright future.

1 INTRODUCTION

The basic pancreatic trypsin inhibitor (BPTI) from bovine pancreas¹ has a molecular weight of 6500 and consists of 58 amino acid residues. The amino acid sequence and the molecular conformation in single crystals² are known, and it has been found that the solution conformation of BPTI is unusually stable towards denaturing agents and heat. Some time ago we briefly discussed proton NMR data which revealed yet another rather unexpected structural feature of BPTI, i.e. very slow exchange of some of the amide protons.³ This paper presents new data on the denaturation of BPTI and the proton exchange in solutions of BPTI in D₂O. An obvious goal of the investigations of BPTI is to understand in more detail the mode of action of this inhibitor. In addition, since BPTI is by its small size amenable to detailed studies by different techniques, work on this molecule could on a more general basis be particularly valuable for the further development of the investigations of molecular conformations in proteins. In view of the temperature stability of BPTI, some of the data on this protein might conceivably even be relevant for the investigation of conformational features in proteins from thermophilic organisms.

This quotation represents the introduction of the first paper from my laboratory that was devoted entirely to BPTI.⁴ We started work on this protein in 1972, and at the time no one could have guessed that I would some day be asked to write an article on BPTI for the *Encyclopedia of Nuclear Magnetic Resonance*. However, the prediction made lightheartedly in 1973, that work with BPTI might be 'particularly valuable' for the future development of research on protein structures, turned out to have been, if anything, an understatement. In the meantime my laboratory has published more than 70 papers on experiments with BPTI and 15 papers on work with chemical modifications and homologs of BPTI, and by now the output of NMR papers on BPTI by other groups exceeds these numbers by far. Outside of the NMR field, BPTI was

one of the first proteins, in 1975, for which a refined high-resolution X-ray crystal structure became available,⁵ which in turn made BPTI a preferred object for theoretical studies on protein structure and dynamics.⁶ At that time BPTI was also already used for studies on protein folding.⁷ In 1982, BPTI was the first protein for which the ¹H NMR spectrum was completely assigned,⁸ which contributed greatly to making it a focal point for research on amide proton exchange in proteins.⁹ More recently, numerous projects on protein-folding studies and amide proton exchange measurements with BPTI relied heavily on the use of NMR for characterization of molecular structures and for kinetic measurements. For the sake of completeness it should also be added that a vast body of literature on the biochemistry and physiology of BPTI provides the platform for the physicochemical and structural investigations.

Figure 1 presents a ribbon drawing of the polypeptide backbone fold in BPTI, and a stereo view of the complete NMR solution structure¹⁰ is shown in Figure 2. The polypeptide backbone forms a 3₁₀-helix from residues 3 to 7, a β -hairpin of residues 18–35, a one-residue third antiparallel β -strand of residue 44, and an α -helix of residues 47–56. There are three disulfide bonds linking the cysteinyl residues 5–55, 14–38, and 30–51. The molecule contains four phenylalanyl residues in positions 4, 22, 23, and 45, and the four tyrosyl residues 10, 21, 23, and 35 as the only aromatic side chains. The arrangement of the polypeptide backbone and the interior side chains (green and blue in Figure 2) is nearly identical in crystals⁵ and in solution.¹⁰ The conformation of the protein surface (red in

Figure 1 Ribbon drawing of the three-dimensional NMR solution structure of BPTI.¹⁰ The three disulfide bonds 5–55, 14–38, and 30–51 are displayed as solid lines tracing the covalently linked side chains. For easy reference some residue positions have been identified. (Drawing prepared using the atom coordinates from Berndt et al.¹⁰)

Figure 2 Stereo view of the NMR solution structure of BPTI represented as a superposition of 20 conformers. All heavy atoms are displayed. Color code: green, polypeptide backbone; blue, core side chains; red, surface side chains. A close fit among the 20 conformers indicates regions of the molecule where the structure is well defined, whereas a large dispersion implicates the presence of (dynamically) disordered structure. (Drawing prepared using the atom coordinates from Berndt et al.¹⁰)

Figure 2) and the surface hydration¹¹ in solution are highly dynamic and different from the X-ray structure because of crystal lattice effects. The globular structure of BPTI is stable over the pH range 2–10 at ambient temperature, and over the temperature range 1–90 °C at neutral pH. Physicochemical studies of the folded protein can thus be performed with extensive variation of the experimental conditions.

2 GROWING UP WITH BPTI

Considering the long years of our involvement with BPTI, it is inevitable that this account has a personal note. There is only one other protein that influenced the activities of my group in a comparable way, i.e. cytochrome *c* (see *Wüthrich, Kurt: NMR Structures of Biological Macromolecules*). However, it was with BPTI that we were introduced to protein structures and the physical chemistry of proteins. When dealing with cytochrome *c* our interest was focused on the one hand on NMR experimentation, and on the other hand on the heme group and its immediate surroundings. For example, all our theoretical work connected with cytochrome *c* and other hemoproteins related to ligand field treatments of the electronic states of the heme iron. With BPTI we became motivated to understand protein structure at a more general level, and through frequent contacts with Robert Huber's group in Munich we also learned about protein crystallography. In particular, during the first 3 years of our NMR work, when we mostly tried to rationalize NMR spectral properties on the basis of the BPTI crystal structure, Deisenhofer and Steigemann⁵ refined the original BPTI structure at 0.15 nm resolution, and we got access to the improvements from the original molecular

model² to the final refined structure in several steps. At that time, the X-ray data were visualized by physical molecular models, and the coordinates were obtained by measuring interatomic distances in these models. I remember a day when local structural features contained in a preliminary set of atom coordinates provided by the Munich group completely upset some calculations in my laboratory. A trip to Munich then revealed that there had been an impact on the BPTI model by an unidentified object (probably a broomstick in the hands of the cleaning personnel) before the atom coordinates were measured. Unimportant as this story is in perspective, it was the kind of experience we needed to develop a realistic view of experimental protein structure determination.

As happens so often with timely research projects, we were not alone in 1973 in starting publishing NMR work with BPTI. Brian Sykes and his co-workers reported studies of the amide protons and the tyrosyl rings,¹² and pursued the investigations of the tyrosyls with the use of chemical modification.¹³ We thus had an opportunity to practice functioning under the pressure of direct competition. Starting around 1975, more and more theoretical work appeared that related directly to our experimental data,⁶ which gave us good motivation to get more thoroughly educated in this area.

3 SURVEY OF KEY NMR EXPERIMENTS WITH BPTI

In Table 1 I have identified 19 key events which have been directly associated with BPTI during the period from the initial NMR experiments with BPTI in 1972^{3,4,12} until the completion of the first NMR structure determination of a protein in

Table 1 Key NMR Experiments with BPTI, 1973–84

Year	Experiment/Observation	Ref.
1973	¹ H NMR of individual amide protons	4, 12
1974	Ring flips of Phe and Tyr	14
1975	Theory of ring flips	6, 15
1976	Sine-bell for digital filtering	16
1977	Homonuclear 2D <i>J</i> -resolved NMR	17
1978	Quantitative NMR studies of amide proton exchange	18–20
1978	Dynamic model for globular proteins	18
1978	Sequential assignments using 1D NMR	21
1979	Mechanisms for amide proton exchange in BPTI	22, 23
1979	SECSY	24
1979	NOESY	25
1980	2D ¹ H NMR with proteins in H ₂ O solution	26
1980	Sequential assignments using 2D NMR	27, 28
1981	NOE build-up measured with 2D NOESY	29
1981	Complete ¹ H NMR assignment of a protein	8
1981	Amide proton exchange in the EX ₁ regime	30, 31
1981	NH trap experiment for detection of early folding events	30, 32
1983	Phase sensitive 2QF-COSY	33
1984	Structure calculation from NMR data using the program DISGEO	34

1984.³⁵ These were either developments of new NMR experiments, important steps toward protein structure determination from NMR data, or NMR observations relating to novel features of protein conformation, and they will be discussed in more detail in the following sections. The selection is based on general considerations of the follow-up activities as reflected, for example, in the citation record, but also on my memory of the impact from these events on our subsequent projects. Table 1 contains mostly references to our own work, since besides several papers on amide proton exchange, mostly by Clare Woodward's group,^{19,22} only seven NMR studies with BPTI were published by others up to 1984. These are four papers by Brian Sykes's group,¹² of which three are on nitrotyrosyl derivatives of BPTI,¹³ two are on refolding of heat-denatured, modified BPTI,³⁶ and a theoretical paper is on chemical shift averaging.³⁷ In addition, by 1984 BPTI was more and more widely used as a standard to check instrument performance.

In recent years in my laboratory, BPTI has lost its pivotal role of the 'heroic era' up to 1984, but elsewhere applications of NMR techniques became more and more widespread in projects on the folding, stability, and dynamics of BPTI (see Section 10 below).

4 BPTI AND NMR SPECTROSCOPY WITH PROTEINS

In the 1970s my group worked mainly with hemoproteins, oligopeptides, and BPTI (see *Wüthrich, Kurt: NMR Structures of Biological Macromolecules*). Among the proteins studied, BPTI was the most robust (see above), and it could be dissolved in water at concentrations up to 20 mM. It is not surprising, therefore, that it was used for most of the NMR technique developments in my laboratory. The first such entry

in Table 1 is the sine-bell,¹⁶ which was of particular practical importance during all those years when absolute value presentations of the 2D NMR spectra were used.^{8,17,24–29} It continues to be widely applied, and is a fitting tribute to the beautiful spectroscopy performed by the late Antonio DeMarco during his all too short life span.

The remaining technique entries refer to early 2D NMR experiments. 2D *J*-resolved spectroscopy had previously been developed in Richard Ernst's laboratory, but the BPTI paper in 1977¹⁷ presents not only the first 2D NMR spectrum of a protein, but also the first 2D spectra recorded with a data size that made the technique useful for practical applications beyond observation of the classical test compounds, such as CH₃I or CH₃CH₂OH. SECSY²⁴ was designed as an alternative to the previously described COSY scheme to overcome limitations imposed by the then available computer capacities. For several years, until phase sensitive 2D NMR became available as a daily routine,^{38,39} the concept of delayed acquisition used in SECSY was widely propagated also by the instrument manufacturers. From our 1D experiments with BPTI²¹ (see also the following section) and cytochrome *c*^{40,41} it was clear in 1978 that NOEs would be the key parameter for studies of macromolecular structures. The first 2D NOESY spectrum on record²⁵ was obtained with BPTI by Anil Kumar in my laboratory during the Christmas recess of 1979. Funding for this project was obtained through a grant application submitted jointly with Richard Ernst in 1978, which requested support for developing improved NOE measurements, including 2D NOESY. Within weeks after the first successful NOESY experiment we recorded homonuclear 2D NMR spectra in H₂O solutions of proteins.²⁶ This was an important step ahead, which enabled the extension of the NMR assignments in the protein core, where the amide protons exchange sufficiently slowly to be observed in D₂O, to the molecular surface. Although the preirradiation used to suppress the solvent line lacks the sophistication of other solvent suppression schemes, it turned out to be exactly what was needed for complete protein structure determinations by NMR. A further fundamentally important advance was to repeat the earlier 1D NMR measurements of NOE build-up curves for BPTI using 2D NOESY.²⁹ BPTI was also used in the first application of a two quantum filter for further improvement of the high-resolution phase sensitive COSY spectra of proteins³³ which we had obtained with the earlier implementation of time proportional phase incrementation (TPPI) by Dominique Marion.³⁸

5 BPTI AND RESONANCE ASSIGNMENTS IN PROTEINS

In 1975, initial resonance assignments in BPTI were obtained for the aromatic region by Brian Sykes's group using chemical derivation of the tyrosyl rings¹³ and in my laboratory using spectroscopic techniques.⁴² In the following years we tried just about any available approach to add assignments for other amino acid side chains in BPTI,⁴³ but the decisive breakthrough that opened the way to NMR structure determination of proteins^{44,45} came in 1978 with the successful 'sequential NOE walk' by Andreas Dubs and Gerhard Wagner for obtaining sequential assignments of the

Figure 3 Stacked-plot representation of a symmetrized, absolute-value 500 MHz ^1H COSY spectrum of a 0.02 M solution of BPTI in a mixed solvent of 90% H_2O and 10% D_2O , pH = 4.6. $T = 80^\circ\text{C}$. The spectrum was recorded in ~ 24 h. The digital resolution is 5.3 Hz/point. Due to the symmetrization the residual perturbations from the water suppression appear as a band of weak peaks parallel to the diagonal. (Reproduced with permission from G. Wagner and K. Wüthrich, *J. Mol. Biol.*, 1982, 155, 347)

β -sheet in BPTI (see Figure 1).²¹ This approach was based on detailed inspection of the BPTI crystal structure (see the following section) and on NMR techniques used previously in our laboratory for a similar sequential walk around the heme group in hemoproteins.⁴⁰ Once the aforementioned 2D NMR experiments were available, the assignments could be extended to other regions of BPTI,^{27,28} and when we obtained a 500 MHz spectrometer in 1981 the complete polypeptide chain in BPTI was assigned.⁸ Figure 3 shows a COSY spectrum from the assignment paper,⁸ illustrating Gerhard Wagner's mastery of the art of NMR spectroscopy with proteins. Over the years this figure has appeared more than 10 times on the cover of books and journals, and a decade after its original publication I was quite surprised to find it also on the EENC poster.

6 BPTI AND PROTEIN STRUCTURE DETERMINATION BY NMR

From joint inspection of NMR data and the high-resolution X-ray crystal structure of BPTI, which was started in a systematic way by Andreas Dubs and Gerhard Wagner in connection with the initial sequential assignment,²¹ we obtained important insights which resulted in a theoretical basis for the sequential resonance assignment technique⁴⁶ and a pattern recognition approach for the identification of secondary structures in proteins.^{47,48} The crucial BPTI contribution to structure calculation from NMR data, however, was the paper with Timothy Havel listed as the last entry in Table 1.³⁴ Using the program DISGEO and simulated input data sets of NOE upper-distance constraints derived from the BPTI crystal structure, this paper demonstrated that complete protein structures at atomic resolution could indeed be obtained from experimental NMR data, and by extensive controlled variation of the simulated input it could also be shown that the method would be robust with respect to incomplete collection

of input data as well as low precision of the individual NOE distance measurements.

Considering the extent to which our activities in the early 1980s were focused on BPTI, the questions must arise why even in 1987 only a low-resolution NMR structure had been published,⁴⁹ and why a complete high-quality structure determination was achieved only in 1992.⁵⁰ An initial BPTI structure calculation from NMR data had indeed already been performed in 1982 by Werner Braun and Gerhard Wagner (unpublished). The software used was an implementation of a metric matrix distance geometry algorithm that had the capacity of handling all-atom structures of oligopeptides with up to about 10 amino acid residues, which had been used successfully for a structure determination of the nonglobular polypeptide hormone glucagon.^{51,52} For the calculations with BPTI a simplified presentation of the polypeptide chain had to be adopted, with each amino acid residue described by two spheres representing the backbone and the side chain, respectively. The fit of the resulting structure with the X-ray crystal structure⁵ was not significantly better than that of model calculations done at the same time by others without use of experimental data. I accepted this outcome as a clear-cut documentation that protein structure calculations from NMR data have to be performed with the complete covalent polypeptide structure to represent properly both the van der Waals constraints and the chirality of the individual residues. We also realized, from comparison with other proteins as well as with simulated input data from the BPTI crystal structure, that we were not obtaining a good quality input of conformational NMR constraints for BPTI. Eventually it turned out that the generally available BPTI preparations contain about 10% of closely related BPTI analogs. Although this did not interfere either with the use of BPTI for the development of NMR techniques or with the resonance assignments, it made the collection of an extensive set of NOE distance constraints as input for a structure determination difficult, since the assignments of many NOESY cross peaks remained ambiguous. Furthermore, work with a recombinant isotope-labeled mutant BPTI also confirmed earlier observations by Gerhard Wagner that some resonance lines were not observed because of conformational exchange, which was now traced to a dynamic equilibrium between the two different chiral forms of the disulfide bridge 14–38 (see Figure 1).⁵³ Based on this information and with the use of a homogeneous protein sample, a high-quality structure determination was finally obtained in 1992.⁵⁰

7 BPTI AND AMIDE PROTON EXCHANGE

Figure 4 shows the first BPTI spectrum published by my laboratory in 1973^{3,4} (comparison with Figure 3 affords a good illustration of the progress made during the following decade), and the high-frequency region illustrates part of an early amide proton exchange measurement. The protein was dissolved in D_2O , and the replacement of individual amide protons by deuterons was followed by measurement of the decrease of the intensities of the corresponding resonance lines with time. In Figure 4, the loss of intensity between the two spectra recorded within 10 min and 170 h after sample preparation, respectively, is readily apparent. This was one of the few experiments with proteins that could be done well in 1973 (see *Wüthrich, Kurt:*

Figure 4 Proton NMR spectrum at 220 MHz of a 0.01 M solution of BPTI in D_2O , $pD = 7.7$, $T = 20^\circ C$. Two spectra were recorded 170 h (a) and 10 min (b) after the preparation of the solution. (Reproduced with permission from A. Masson and K. Wüthrich, *FEBS Lett.*, 1973, **31**, 114)

NMR Structures of Biological Macromolecules), and so we started to collect exchange data with BPTI under a wide variety of conditions of pH, temperature, and ionic strength, and subsequently also with homologs and chemical modifications of BPTI.

Amide proton exchange measurement has been a classical approach in protein chemistry long before any such studies were started with BPTI, dating back to the days of the Linderstrøm–Lang laboratory in Copenhagen.⁵⁴ The NMR measurements with BPTI added a new element in that the exchange from individual sites in the protein could be followed, whereas earlier techniques yielded information only on the percentage of the ensemble of all amide protons that had exchanged after a certain time span.⁵⁴ The new potentialities of NMR were soon recognized by those specializing in the field of amide proton exchange,⁵⁵ and in particular Clare Woodward and her group^{19,22} started to perform NMR exchange measurements with BPTI under a wide range of conditions. The follow-up to the NMR studies on amide proton exchange listed in Table 1^{18–20} continues to the present, and the mechanisms for amide proton exchange in BPTI proposed in 1979^{22,23} provide a much discussed background.

The next advance came with the individual assignments of amide proton NMR lines,²¹ so that exchange rates could be attributed to unique sites in the BPTI crystal structure.^{20,23} This step was completed in 1982, when a map of all individual exchange rates in BPTI was obtained.⁵⁶ The last entry on this topic in Table 1^{30,31} covers experiments by Heinrich Roder in which experimental conditions were identified where the exchange in a chemically modified BPTI derivative proceeds via a so-called EX_1 process, so that the exchange rates are directly related to the frequencies of protein structure fluctuations.⁵⁴ This paper shows that EX_1 processes for amide proton exchange in proteins can be obtained only under extreme conditions which are not normally used for exchange measurements. Therefore, nearly all available exchange data are governed by EX_2 processes, where the exchange rates are not directly related to the frequencies of internal motions in the protein structure but rather to the acid/base-catalyzed reaction at the amide group modulated by conformational equilibria in the protein.²³

8 BPTI AND INTERNAL MOBILITY IN PROTEINS

In the X-ray crystal structure of BPTI the aromatic rings of phenylalanine and tyrosine are among the side chains with the smallest temperature factors.⁵ For each ring the relative values of the B -factors increase toward the periphery, so that the largest positional uncertainty is indicated for the C-4 position on the symmetry axis through the $C\beta$ – $C\gamma$ bond. The observation of ring-flipping motions on the millisecond to microsecond timescale (Figure 5)¹⁴ was therefore a genuine surprise, since it appeared to be incompatible with the crystal structure. Theoretical studies performed in a collaboration of my group with Robert Huber's laboratory,¹⁵ and independently by Martin Karplus's group⁶ then showed that the crystallographic B -factors sample multiple rotation states about the $C\alpha$ – $C\beta$ bond, whereas the ring flips about the $C\beta$ – $C\gamma$ bond seen by NMR are very rapid 180° rotations connecting two indistinguishable equilibrium orientations of the ring. The B -factors do not manifest these rotational motions because the populations of all nonequilibrium rotational states about the $C\beta$ – $C\gamma$ bond are vanishingly small. The ring flip phenomenon, which turned out to be a general feature of globular proteins, thus showed that there are low-frequency internal motions in protein molecules, which have activation energies of 60–100 kJ mol^{−1} and amplitudes of $\gtrsim 0.1$ nm, and involve concerted displacements of numerous groups of atoms. Ring flips have since been the subject of a long series of theoretical and experimental investigations.

Working with a series of chemical modifications of BPTI and homologous proteins, we observed in 1978¹⁸ that amide proton exchange rates measured under conditions of EX_2 exchange are correlated with the thermal stability of the protein, i.e. corresponding protons would exchange more rapidly in the less stable proteins. In contrast, the ring flip rates, which are directly related to the frequencies of internal protein structure fluctuations, were found to be insensitive to protein stability as long as the 3D structure was preserved at the conditions of the experiment.

BPTI continues to be a source of observations on dynamic features which turn out to be common to globular proteins at large. Most important, it was with BPTI that we succeeded in 1989 in observing individual molecules of hydration water by NMR,⁵⁷ to demonstrate that internal hydration water molecules exchange with the bulk solvent on a millisecond timescale or faster,⁵⁸ and to distinguish qualitatively between interior hydration sites and surface hydration,¹¹ which provides a rationale for the generally observed dynamic surface disorder in NMR solution structures of globular proteins (see Figure 2). Another novel dynamic feature identified recently in BPTI is the aforementioned slow interconversion between two conformation states of the disulfide bond 14–38,⁵³ which was also clearly manifested in ^{15}N $T_{1\rho}$ measurements.⁵⁹

9 BPTI AND PROTEIN FOLDING

One of the 1981 entries in Table 1 is the amide proton trap experiment for studies of early events in protein refolding, which was performed as part of Heinrich Roder's Ph.D. thesis in 1981.^{30,32} This experiment and refined forms thereof became very popular in the late 1980s, and it is now one of

Figure 5 1D 360 MHz ^1H NMR spectra at variable temperature of a 0.01 M solution of BPTI in D_2O , $\text{pD} = 7.8$. The region from 6.0 to 8.5 ppm is shown. The resonances of the aromatic rings of Phe-45 (○) and Tyr-35 (▲) were simulated in the center and on the right, respectively, using the ring flip frequencies indicated with the individual spectra. The resonance assignments in the simulated spectra refer to the standard numeration for the aromatic rings of phenylalanine and tyrosine. (Reproduced by permission of Wiley from K. Wüthrich, 'NMR of Proteins and Nucleic Acids', 1986)

the standard techniques in laboratories working on the protein-folding problem.

As mentioned in the introduction, BPTI has long played an important role in the area of protein folding,⁷ and early attempts to use NMR experiments for folding studies have already been cited.^{32,36} More recently, NMR has been used extensively for structural characterization of BPTI folding intermediates containing only part of the native disulfide bonds (see Figure 1), mainly in the laboratories of Thomas Creighton⁶⁰ and Peter Kim.⁶¹

10 CONCLUDING REMARKS

BPTI has been a focal point for my research group from 1973 until about 1984, when our main activities shifted away from method development toward applications of NMR for protein structure determination in a variety of different systems. This article covers mainly the period of our intense involvement with this protein. Around 1985 we undoubtedly had a feeling of saturation with BPTI, which was also nurtured

by referee comments on 'yet another paper on BPTI'. Things were rather quiet for several years after 1985, but in the late 1980s research with BPTI picked up momentum again, triggered primarily by the production of recombinant mutants of BPTI and the possibility of labeling the recombinant proteins with isotopes. Although crystal structures of at least 10 BPTI mutants have been described during the last few years, most of the structural work is done using NMR in connection with folding studies.^{60,61} These were recently very much in the limelight due to a widely publicized controversy between Thomas Creighton and Peter Kim on certain aspects of the BPTI refolding pathway. Listening to a presentation by Clare Woodward at the 1994 Annual Meeting of the US Biophysical Society I also learned that the correlation between thermal stability of the folded protein and amide proton exchange rates^{18,23} is being further investigated with the use of recombinant BPTI mutants. Overall, considering the advanced techniques now available for protein preparation and NMR investigations, we can look forward to many more years of excitement in research with BPTI.

1 INTRODUCTION

During the last several years there has been a revolution in the use of NMR to study proteins and nucleic acids in solution (see Wüthrich¹). In principle, NMR offers the ability simultaneously to observe each hydrogen, carbon, and nitrogen atom in a protein or nucleic acid in a variety of solution environments. Very detailed structural information can be obtained by using a form of dipolar energy transfer between nuclear spins (nuclear Overhauser enhancements or NOEs) to monitor the distance between those atoms on a 1–5 Å scale. Bonding and torsion angle information can be obtained by monitoring the through-bond scalar couplings between nuclear spins. In addition, information concerning the rates of molecular fluctuations and chemical reactions can be obtained by measurement of the relaxation properties of the nuclear spins and the exchange of amide protons with solvent.

In the past, it had been difficult to gain access to this wealth of information. There are three difficulties that must be overcome. The first is spectral resolution. A typical protein of 150 amino acid residues contains about 1100 protons, 750 carbon atoms, and 180 nitrogen atoms. While ¹H, ¹⁵N, and ¹³C resonate at very different frequencies, the overlap of the various ¹H, ¹⁵N, and ¹³C resonances with others of their kind is severe. The second fundamental difficulty concerns the assignment of the large number of overlapping resonances to individual atoms in the macromolecule of interest. The third difficulty concerns the relatively low sensitivity of detection of NMR signals. This is an especially serious problem for ¹⁵N and ¹³C since these nuclei are relatively poorly detected and these isotopes are present in only about 1% natural abundance.

There have been remarkable advances in the development of new and very powerful strategies to overcome all these problems. Here we will discuss some of these approaches and their applications to problems concerning protein structure, the dynamics or ‘breathing’ motions of proteins, and the elucidation of the kinetic pathway by which an unfolded, random coil, linear polymer of amino acids folds to become a functional, folded molecule.

2 SPECTRAL RESOLUTION AND RESONANCE ASSIGNMENT

The development of two-dimensional (2D) ¹H NMR made it possible to study small proteins and oligopeptides. This greatly increases the resolution of the experiment and many individual proton resonances can be resolved. In addition, the through-space (NOE) and through-bond interactions exploited to produce the 2D spectrum provide structural information directly. However, the complexity of the ¹H spectra of proteins of more than 100 residues makes it very technically challenging to assign and analyze these spectra of proteins of this size or larger. Larger proteins require the increased resolution available by dispersion of the resonances in three or four dimensions. Typically this requires the biosynthetic incorporation of ¹⁵N and/or ¹³C isotopes into the protein and the use of these nuclear spins to provide the additional dimensionality required for reasonable resolution (see, for example, Fesik and Zuiderweg,² Marion et al.,^{3,4} Ikura et al.,⁵ Kay et al.,^{6,7} and Boucher et al.⁸). The increased resolution and the nature of the interactions exploited in the experiments make these approaches very well suited to the assignment and analysis of proteins of 100–300 residues. The upper limit is an estimate and may be somewhat optimistic. Importantly, these approaches begin to gain access to a number of proteins with interesting and important activities.

3 T4 LYSOZYME AS A SYSTEM FOR STUDYING PROTEIN FOLDING

In general, the primary amino acid sequence of a polypeptide chain is thought to encode all the information necessary to determine the final folded structure of a protein. However, the contributions made by individual amino acid residues to the overall structure, dynamics, and stability of the folded protein as well as the role(s) of individual residues in the kinetic pathways between the unfolded and folded states remains less clear. In recent years, there has been a substantial amount of progress in addressing these questions (e.g. Bowie et al.,⁹ Alber,¹⁰ Dill,¹¹ Lim and Sauer,¹² Pace et al.,¹³ Kim and Baldwin,¹⁴ Goldenberg et al.,¹⁵ and Matthews¹⁶). The lysozyme produced by bacteriophage T4 offers an excellent experimental system to address these important questions. In addition, the collaborative research efforts of the Matthews (crystallography, structural bases of protein stability), Schellman (thermodynamics), Hudson (nanosecond dynamics), and our laboratories at the University of Oregon offer a nearly unique environment for the investigation of these issues.

The lysozyme from bacteriophage T4 is a 164-residue (18 700 dalton), single-chain polypeptide. As shown schematically in Figure 1, the protein is folded into a bilobed structure centered on a 19-residue α -helix.¹⁷ The protein is primarily composed of helical secondary structure, but also contains a small antiparallel β -sheet in the N-terminal lobe. Figure 2 shows the amino acid sequence of the protein with the α -helices indicated with the letters A–H. The C-terminal domain contains the first helix (helix A) of the N-terminus of the protein.

Figure 2 The amino acid sequence of wild-type T4 lysozyme. The α -helical regions are indicated with the letters A–H. The region H consists of two α -helices separated by threonine-141 and proline-142. In addition there are two distorted α -helical segments corresponding to residues 107–113 and the C-terminus

A wide variety of mutations have been introduced into the protein. These include the replacement of the two cysteine residues to produce a thiol-free version of the wild-type protein with nearly identical thermodynamic stability as the original,¹⁸ introduction of new disulfides at several positions, which usually increases the thermodynamic stability of the protein,¹⁹ and a host of systematic changes introduced at many positions to investigate hydrophobic,²⁰ electrostatic,²¹ core packing,²² and hydrogen-bonding interactions.²³ The great majority of these mutant proteins have been crystallized and their crystal structures have been determined in the Matthews laboratory. To date the structures of about 150 T4 lysozyme variants have been determined. Some of these involve different crystal packing arrangements,^{24,25} and have allowed seven distinct views of the protein to be obtained. In addition Poteete's laboratory has recently developed a genetic system in which

T4 lysozyme is used to complement a lysozyme-deficient P22 bacteriophage.²⁶ Using this system Poteete and co-workers have described the complementation properties of a huge collection of lysozyme variants in which residues 2–164 have each been replaced by 13 different residues using nonsense suppressors. This provides a qualitative indication of the activity and stability of these variants, which can be very useful in the design of new lysozyme variants. Finally, a very efficient bacterial expression system allows the isolation of about 50 mg of pure protein from a liter of minimal medium.²⁷ To date this expression system has produced proteins from about 300 lysozyme variants in quantities suitable for physical studies. Thus the T4 lysozyme system offers an excellent opportunity to examine the interrelationships of amino acid sequence, structure, stability, and dynamics.

We have published the assignments of the proton and ^{15}N magnetic resonance spectra of the backbone and about 25% of the side-chain protons of wild-type T4 lysozyme²⁸ and these are shown in Figure 3. The Figure shows a heteronuclear multiple quantum coherence (HMQC) spectrum²⁹ in which each cross peak represents an ^{15}N –H directly bonded pair in the protein. The ^{15}N and H coordinates of each cross peak correspond to the chemical shifts of the ^{15}N and proton environments of the pair.

This paper describes some of the recent work from our laboratory, which is directed toward understanding the dynamics of the folded state, and the kinetic path used by the protein while it folds. Much of this work takes advantage of some of the recent advances in high-resolution NMR as applied to biological systems. When combined with site-directed mutation, thermodynamic analysis, and rapid X-ray diffraction analysis of mutant structures, questions in these areas can often be addressed with exquisite sensitivity at atomic resolution.

4 CORE PACKING MUTANTS AND DYNAMIC ACCESS TO THE HYDROPHOBIC CORE

Recently, the Matthews laboratory has discovered that several mutations in which bulky side chains in the hydrophobic core are replaced by smaller side chains can create or expand apparent cavities in the core.^{22,30} In the case of the mutation L99A, replacement of the leucine side chain by a methyl group expands an existing cavity in the core of the C-terminal domain. The mutant protein is substantially destabilized when compared with its wild-type. They found that some of these mutant proteins can bind hydrophobic compounds such as benzene in the apparent cavities.³¹ This binding has been detected as a benzene-dependent stabilization of the mutant proteins toward reversible unfolding and has also been detected by the observation of bound benzene molecules in the crystal structures of these mutant proteins in the presence of benzene.

We have examined the effects of these apparent cavity mutants on the dynamic properties of T4 lysozyme in solution. Baldwin, working in the Matthews laboratory, has constructed a series of alanine substitution mutants for residues 94–106. The mutants that bind benzene in the core include L99A, F104A, M102A, and two substitutions outside the E helix, L133G and F153A. The mutations L99A, M102A, and N101A all create apparent cavities that have no static route allowing access to the cavity by a molecule of the bulk solvent.

applied to several proteins including ribonuclease A,^{32,33} egg-white lysozyme,³⁴ cytochrome *c*,³⁵ ubiquitin,³⁶ and barnase.³⁷

Measurement of hydrogen–deuterium exchange rates of amide protons is a sensitive probe for the presence of structure in a fully or partially folded protein. The formation of hydrogen bonds such as those seen in α -helices or β -sheets dramatically reduces hydrogen–deuterium exchange rates of amide protons. In a typical pulse hydrogen-exchange experiment (see Robertson and Baldwin³⁸), refolding of a deuterated protein is initiated in D₂O and a ‘snapshot’ of the protein is taken at different times after refolding by subjecting the sample to a proton-labeling pulse of H₂O at high pH to label rapidly those amides that remain exposed at that particular time. After allowing the protein to refold under conditions where hydrogen exchange is slow, 2D ¹H,¹⁵N NMR is then used to determine which amide protons are protected at various times during the folding process.³⁹

When folding is initiated, the native, folded structure is produced in about 150 ms. However, selected parts of the amino acid sequence form structure as soon as we take the first data point at 10 ms. It appears that most, if not all, of the molecules form an intermediate or a population of intermediates that is characterized by significant protection from solvent exchange. This behavior is observed at 25–30 residues with varying degrees of protection at early times.

This information is presented in Figure 4 as a plot of relative protection factor versus position. These data clearly demonstrate that three regions are protected from amide exchange within 30 ms of folding. The calculated relative protection factors are at least 20 and vary to a maximum of 300 for the residues in three regions of the sequence, corresponding to residues 5–13 (helix A), those near residue 20 of the N-terminal domain β -sheet, and residues 96–105 (helix E). The most protected residues, contained in the β -sheet in the N-terminal domain and in helix A and helix E in the C-terminal domain, are protected about 100-fold relative to free amides. Protection factors of similar magnitude were observed in the partly folded apomyoglobin structure formed under

equilibrium conditions by Hughson et al.⁴⁰ Such behavior is consistent with the formation of relatively isolated regions of secondary structure.

The region of the protein that shows the highest degree of protection from hydrogen exchange corresponds to residues 95–103. This region corresponds to helix E in the native structure of the protein. The crystal structure of the native state shows that this helix is the most buried. It is reasonable that this helix forms earliest during refolding. Helix A is in close contact with helix E and amide-hydrogen exchange is also slow in helix A. It is possible that these early protected regions form a structure for the subsequent refolding of the entire protein.

The stability of the folded state of T4 lysozyme can be modified both by low pH values and by mutational substitutions of side chains. Morton has used both pH and the mutation F153A to lower the stability of the protein such that it unfolds at room temperature in the absence of denaturant. Under these conditions, the protein appears to form a ‘molten globule’ state in which there is still significant α -helical content, as judged by circular dichroism. The protein does not appear to have much tertiary structure, as evidenced by very little if any dispersion in side-chain chemical shift. This molten globule state bears significant similarity to the kinetic folding intermediate discussed above. This suggests that the kinetic intermediate we detect using the pulsed hydrogen-exchange approach may reflect the most stable form of the unfolded state when the protein is placed in conditions that strongly favor folding. These molten globule states are usually not seen at equilibrium because such conditions strongly favor the folded state.

If this reasoning is correct, the kinetic properties of the folding reaction should reflect the free energy differences between the molten globule, unfolded state, and the overall transition state for the folding reaction. We have used this model to interpret our recent observations involving a series of mutations in the C-terminal domain core, that all slow folding occurs by a significant amount. The side chains of these residues all appear to participate in the formation of the core during the rate-limiting step for the folding reaction. Our observations suggest that the dominant folding pathway of the wild-type protein involves the formation of this hydrophobic core in the C-terminal domain during the major rate-limiting step for folding. In mutants in which the core is destabilized by removal of hydrophobic surface area, other kinetic paths become the dominant paths. In some cases it appears that events in the N-terminal domain may become rate-limiting or co-rate-limiting. These observations argue that there are likely to be a number of competitive pathways for a given protein to fold. If one or another of these paths are made less favorable the protein still reaches its most thermodynamically favored state but uses an alternative path.

Figure 4 The amide exchange properties of the unfolded state of T4 lysozyme expressed as the calculated protection factor versus position at pH 2.4, 30 °C, and in 3.0 M urea. The protection factors are calculated as the ratio of the observed first-order rate constant for exchange for each residue as compared with a theoretical value that accounts for the pH of the sample, the presence of urea, and the effects of adjacent residues. 1 INTRODUCTION

Triple resonance (^1H , ^{13}C , ^{15}N) NMR techniques¹ have greatly reduced the effort required to obtain protein signal assignments as well as interproton distance and dihedral angle restraints.² This development has enhanced the prospects of obtaining information about protein structure. Such information is of widespread interest because it is fundamental for understanding protein function. However, proteins are not rigid bodies, but rather execute internal motions on a wide range of timescales.³ In order to understand important aspects of protein function such as folding, molecular recognition, and enzyme action, detailed knowledge about protein dynamics is essential. At a more fundamental physical level, experimental information about the amplitudes and rates of internal motions in proteins can be used to check the predictions of molecular dynamics trajectories. Such tests of theoretical calculations should result in improved formulas for the potential functions used in the computations.

Protein structures in solution are derived using restraints obtained almost exclusively from proton J couplings and NOEs,^{4,5} whereas information about the internal motions of proteins is derived most directly from measurements of spin relaxation rates of nuclei such as ^{15}N and ^{13}C (designated A spins herein).^{6–8} Although ^{13}C relaxation studies of proteins were initiated over a decade ago,⁸ these early studies were limited by the lack of sequential assignments as well as by the low resolution and sensitivity afforded by one-dimensional NMR spectra recorded with A spin detection. Fortunately, triple resonance experiments¹ provide sequential assignments of ^{15}N and ^{13}C nuclei along with those of protons. Hence, proton-detected two-dimensional heteronuclear relaxation experiments^{9–16} are a means of measuring A spin relaxation rates with high sensitivity and resolution.

2 THEORETICAL CONSIDERATIONS

2.1 Relaxation Equations

Elegant general formalisms relating nuclear spin relaxation to molecular motion have been provided by Abragam¹⁷ and Redfield.¹⁸ In the case of a spin $I = \frac{1}{2}$ A nucleus such as ^{13}C or ^{15}N directly bonded to N protons (designated X), the AX_N dipolar interactions and A-spin chemical shift anisotropy, CSA, are the significant relaxation mechanisms. Provided that cross correlations can be neglected, the A-spin longitudinal relaxation time, T_1 , transverse relaxation time, T_2 , and A- $\{\text{X}\}$ NOE, are given by^{9,17}

$$1/NT_1 = d^2[J(\omega_A - \omega_X) + 3J(\omega_A) + 6J(\omega_A + \omega_X)] + c^2J(\omega_A) \quad (1)$$

$$1/NT_2 = 0.5d^2[4J(0) + J(\omega_A - \omega_X) + 3J(\omega_A) + 6J(\omega_X) + 6J(\omega_A + \omega_X)] + \frac{1}{6}c^2[4J(0) + 3J(\omega_A)] \quad (2)$$

$$\text{NOE} = 1 + (\gamma_A/\gamma_X)d^2[6J(\omega_A + \omega_X) + J(\omega_A - \omega_X)]NT_1 \quad (3)$$

where ω_i is the Larmor frequency of spin i , $J(\omega)$ is the spectral density function, γ_i is the gyromagnetic ratio of spin i , $d^2 = 0.1[(\mu_0/4\pi)\gamma_A\gamma_Xh/(2\pi\langle 1/r_{\text{AX}}^3 \rangle)]^2$, $c^2 = \frac{2}{15}[\omega_A(\sigma_{\text{vert}} - \sigma_{\perp})]^2$, h is Planck's constant, r_{AX} is the AX bond length (0.102 nm for NH and 0.109 nm for CH), and $\sigma_{\parallel}$ and $\sigma_{\perp}$ are principal components of the axially symmetric CSA tensor. For the amide ^{15}N , the CSA is about 160 ppm,¹⁹ and at 11.7 T contributes nearly 20% to the ^{15}N relaxation rate. In contrast, the CSA contribution is much smaller in the case of aliphatic carbons. For example, the CSAs of rotating methyl and backbone α -carbons are about 25 and 35 ppm respectively, and, at 11.7 T, contribute less than 2.5% to ^{13}C spin relaxation.

As noted above, equations (1)–(3) are valid only when the effects of cross correlations are negligible. Although rf pulses can eliminate cross correlation of AX dipolar A-spin CSA interactions,¹¹ such pulses cannot completely eliminate the effects of dipolar cross correlations in AX_2 and AX_3 spin systems.²⁰ In general, A-spin magnetization relaxes in multiexponential fashion in AX_2 and AX_3 spin systems, and equations (1) and (2) yield the initial decay rates of longitudinal and transverse magnetization, respectively.²⁰

2.2 The Model-Free Formulation of the Spectral Density Function

In equations (1)–(3), the spectral density function contains the information about molecular motion. However, if experiments are recorded at a single external field, only three experimental parameters are measured, and hence the data are insufficient to determine the spectral density function at five frequencies. In principle, spectral densities at 11 frequencies can be determined from the set of 12 A-spin T_1 , T_2 , and NOEs measured at four magnetic fields: $\gamma_A\omega$, $\gamma_H\omega$, $(\gamma_H \pm \gamma_A)\omega$, where ω is the A-spin Larmor frequency at the lowest

field employed. However, the large value of γ_H/γ_A , requires that one data set be obtained at low field (<3.5 T) where sensitivity and resolution are poor. Spectral densities have been determined for eglin c from spectra recorded at a single high field by measuring an expanded set of relaxation parameters that include the relaxation of certain two-spin coherences and the selective proton longitudinal relaxation.¹⁶ A potential limitation of this approach is that the relaxation of the two-spin coherences contain a large contribution from the selective proton relaxation. This contribution must be subtracted from the two-spin relaxation in order to obtain reliable values of $J(\omega_i)$.

An alternative to direct determination of the spectral density functions is afforded by the model-free approach.^{6,7} According to this formalism, the spectral density function is expressed in terms of three motional parameters according to

$$J(\omega) = S^2 \tau_m / (1 + \omega^2 \tau_m^2) + (1 - S^2) \tau / (1 + \omega^2 \tau^2) \quad (4)$$

where S is the generalized order parameter, τ_m is the overall correlation time, and $1/\tau = 1/\tau_m + 1/\tau_e$, where τ_e is an effective correlation time characterizing the internal motions of the protein. Equation (4) is an exact expression provided that (a) the overall motion of the protein is isotropic and is not correlated with the internal motions, and (b) all correlation times associated with the internal motions are in the extreme narrowing limit. When internal motions take place on two significantly different timescales, a useful, approximate, generalization of equation (4) is

$$J(\omega) = S^2 \tau_m / (1 + \omega^2 \tau_m^2) + (1 - S^2) \tau_1 / (1 + \omega^2 \tau_1^2) + S_f^2 (1 - S_s^2) \tau_2 / (1 + \omega^2 \tau_2^2) \quad (5)$$

where S_f , τ_1 and S_s , τ_2 are order parameters and effective correlation times associated with the ‘fast’ and ‘slow’ (outside the extreme narrowing limit) internal motions, and $S = S_f S_s$.²¹

The analysis of relaxation data using the model-free approach yields the overall correlation time of the protein as well as values of S^2 and τ_e for individual amino acid residues in the protein. Because τ_e is, in general, a complex combination of geometric factors and internal correlation times it cannot be interpreted in a quantitative manner. However, its determination does provide an estimate of the timescale of the internal motion at a particular site in the protein. In contrast, the order parameter is precisely related to the amplitude of the internal motion.^{6,7} When the interaction responsible for relaxation is axially symmetric, with the symmetry axis along the AX bond, (rigorously true for the AX dipolar interaction and approximately so for the ^{15}N amide CSA interaction) S^2 is given by

$$S^2 = \int d\Omega_1 p_{\text{eq}}(\Omega_1) \int d\Omega_2 p_{\text{eq}}(\Omega_2) P_2(\cos \theta_{12}) \quad (6)$$

where $p_{\text{eq}}(\Omega) d\Omega$ is the equilibrium probability that the unit vector along the AX bond axis has orientation $d\Omega$, $\Omega = (\theta, \phi)$, in a coordinate system fixed in the protein, θ_{12} is the angle between two such vectors, and $P_2(x) = (3x^2 - 1)/2$. The advantage of the model-free approach derives from the fact that values of S^2 are obtained for numerous sites in the protein without the need to assume an explicit model of the internal motion. Using equation (6) values of S^2 can be

calculated for any model of interest. Then, it can be determined if the model does indeed yield order parameters in agreement with experiment, and if the order parameters correspond to physically reasonable values of angular amplitudes of internal motion.

A useful and popular model of internal motion is diffusion in a cone, in which the AX bond axis is thought to diffuse freely in the angular region $0 \leq \theta \leq \theta_0$, $0 \leq \phi \leq 360^\circ$, where θ and ϕ are spherical, polar angles. For this model,

$$S^2 = [0.5 \cos \theta_0 (1 + \cos \theta_0)]^2 \quad (7)$$

so that the cone semiangle can be derived from the order parameter. Equation (7) reveals several general features about the relationship between the amplitude of angular reorientation and S^2 . S^2 equals unity when θ_0 is zero, diminishes as θ_0 increases, and vanishes when $\theta_0 = 180^\circ$, i.e., isotropic motion. Note however that S^2 is not a monotonic function of θ_0 , and vanishes when motion is not isotropic, $\theta_0 = 90^\circ$. In general, S^2 is large for a small amplitude motion, but the converse need not be true; for example, S^2 equals unity if the AX bond reorients by a two-site jump of 180° . Analytical expressions for S^2 are available for other plausible models of internal motion.^{6,7}

3 PULSE SEQUENCES AND DATA ANALYSIS

Two-dimensional heteronuclear pulse sequences designed to measure A-spin T_1 , T_2 , and NOE values in AX spin systems ($A = ^{13}\text{C}$ or ^{15}N , $X = ^1\text{H}$) are depicted in Figure 1.^{9,14} In order to maximize sensitivity, A-spin magnetization is derived from proton magnetization using an INEPT scheme in the T_1 and T_2 pulse sequences, and proton detection is employed in all three experiments. The application of 180° proton pulses during the relaxation delay period, T , suppresses cross correlation of AX dipolar and A-spin CSA interactions. The NOE experiment is the least sensitive of the three measurements because one must record spectra starting with equilibrium A-spin magnetization (in the absence and presence of proton saturation), and it is necessary to wait a long period between scans ($\geq 3T_L$, where T_L is the larger of either the proton or the A-spin T_1 value) to ensure that the A-spin magnetization attains equilibrium. Also, when the spectrum is recorded in H_2O without a NOE, water saturation must be achieved quickly in order to minimize transfer of saturation from water to protein protons. Recently it has been shown that one can avoid water saturation in the NOE experiment using pulsed field gradients and water flip-back pulses.²²

Pulse sequences for measuring methyl ^{13}C relaxation parameters, while similar to those depicted in Figure 1, differ from them in several significant respects.^{12,13,23} First, one must use magic angle delays in INEPT- or DEPT-type transfer steps in order to avoid complications that arise from dipolar cross correlations¹² and to ensure that carbon magnetization in $\frac{3}{2}$ and $\frac{1}{2}$ proton manifolds is faithfully transferred back to protons¹³ in the reverse INEPT or DEPT portions of the sequences. Second, a sequence of 125° proton pulses should be applied during the CPMG period in order to eliminate dipolar cross correlations from ^{13}C transverse relaxation within the $\frac{3}{2}$ manifold. Third, the final delays, Δ , in the reverse INEPT portion of the sequence should be set to a short value, about

Figure 1 Pulse sequences used to measure A-spin (a) T_1 , (b) T_2 , and (c) A{-X} NOE in AX spin systems. The sequences are discussed in Kay et al.¹⁴

$1/[8J(C, H)]$, to minimize the effect of rapid proton relaxation upon the measurement of the ^{13}C relaxation rates. Finally, because the methyl ^{13}C NOE is large, there is no sensitivity loss in saturating the protons and initiating the T_1 and T_2 experiments with ^{13}C magnetization. Sequences for measuring methyl carbon relaxation have been discussed in detail,^{12,13,23} and Kay et al.¹³ have discussed the errors in T_2 measurements that are caused by (a) missetting the magic angle, and (b) rapid relaxation of proton magnetization in the $\frac{3}{2}$ manifold, when INEPT- and DEPT-type sequences are recorded without applying 125° pulses during the CPMG period. Application of 125° pulses, during the CPMG period, decreases (increases) the error in the T_2 measurement in the INEPT (DEPT)-type experiment caused by magic angle misset, and increases (decreases) error in the INEPT (DEPT) experiment caused by rapid proton relaxation.

Although the pulse schemes used to measure methyl relaxation minimize the effects of dipolar cross correlation, rf pulses cannot mix the $\frac{3}{2}$ and $\frac{1}{2}$ proton manifolds and therefore cannot completely eliminate such effects. Fortunately, dipolar cross correlations make very small contributions to T_1 and NOE of rapidly rotating methyl carbons in proteins in the 5–40 kDa molecular weight range.²⁴ Hence, equations (1) and (3) can be applied in the analysis of methyl carbon relaxation in proteins. However, the effects of dipolar cross correlations are significant in the case of transverse relaxation, and equation (2) provides the rate of the initial decay of

the methyl carbon transverse magnetization. Finally, we note that chemical exchange often contributes to T_2 relaxation in proteins. Because accurate T_2 values are obtained by the CPMG method only when $\delta \ll 1/[2J(A, X)]$,^{9,14,16} small δ values are employed in the CPMG sequence. For this reason, and because the maximum spin lock field that can be safely applied to protein solutions is about 10 kHz, chemical exchange often affects T_2 and $T_{1\rho}$ in a similar way. Therefore, even in the presence of chemical exchange, T_2 may be equal to $T_{1\rho}$. A significant increase in $1/T_2$, as the external field increases, is strong evidence that fast chemical exchange contributes to transverse relaxation.

In view of the large amount of data that is required to determine residue-specific relaxation parameters in proteins, surface fitting routines are an extremely useful means of determining signal positions and intensities in individual two-dimensional spectra. The derived signal intensities are fit to an equation of the form $y = A \exp(-t/T_i)$, $i = 1, 2$, using conjugate gradient minimization techniques,²⁵ and standard errors in A and T_i are obtained using a Monte Carlo approach.²⁶ The NOE values are determined by measuring the ratio of signal intensities in the presence and absence of proton saturation. The standard error in the NOE measurement is derived from the rms noise measured in a signal-free region of the spectrum.

Although the model-free approach can be applied when the overall motion of the protein is anisotropic,^{6,7,27} most globular

proteins have approximately spherical shapes, and it is usually assumed that the overall motion of the protein is characterized by a single overall correlation time, τ_m . In the framework of the model-free formalism, each NMR parameter is then related to three parameters: the global parameter τ_m , and two residue-specific internal motion parameters, S^2 and τ_e . A general approach to determine the three model-free parameters consists of minimizing the function^{25,28,29}

$$\chi^2 = \sum_i \{[(T_{1i}^{\text{obs}} - T_{1i}^{\text{cal}})/\sigma_{1i}]^2 + [(T_{2i}^{\text{obs}} - T_{2i}^{\text{cal}})/\sigma_{2i}]^2 + [(\text{NOE}_i^{\text{obs}} - \text{NOE}_i^{\text{cal}})/\sigma_{\text{NOE}_i}]^2\} \quad (8)$$

where the summation is over the residues in the protein, the superscripts indicate observed and calculated parameters, and σ is the standard error in the measured parameter. A single value of τ_m is assigned to all residues in the protein and then the set of $\{S_i^2, \tau_{ei}\}$ values that minimize χ^2 is found using conjugate gradient minimization.²⁵ This process is repeated, incrementing τ_m until the minimum value of χ^2 is attained. Then, several hundred synthetic data sets are used in a Monte Carlo approach^{23,26,29} to determine the uncertainties in the model-free parameters.

In analyzing relaxation data, residues that have unusually small T_2 values should be noted, because a small T_2 suggests that chemical exchange contributes to transverse relaxation. In contrast, unusually large T_2 values indicate the presence of large-amplitude, rapid internal motions that may not be well fit by a single internal correlation time. It is probably best to exclude residues with unusual T_2 values from the initial determination of τ_m using equation (8). Once the value of τ_m is determined, residues having anomalous T_2 values can be analyzed to see if an exchange term is required to account for a small T_2 or if an analysis involving more than one internal correlation time is required to account for relaxation data of residues having large T_2 values. An approach has been presented,²⁹ based upon statistical criteria, for systematically adding parameters to analyze relaxation data within the framework of the model-free formalism.

4 TWO-DIMENSIONAL HETERONUCLEAR RELAXATION STUDIES OF PROTEINS

4.1 Staphylococcal Nuclease (SNase)

Staphylococcal nuclease is a 17 kDa phosphodiesterase that efficiently hydrolyzes strands of both DNA and RNA. Relaxation studies of a uniformly ^{15}N -labeled protein yielded an overall correlation time of 8.3–8.5 ns,³⁰ while ^{13}C relaxation measurements³¹ of samples labeled at alanine (Ala) C- α sites yielded a somewhat larger value of τ_m in the range 9.2–9.5 ns. The larger value of τ_m , obtained from the carbon relaxation data has been ascribed to the fact that the viscosity of the solvent (D_2O) is about 20% greater than the solvent (H_2O) used in the ^{15}N study. The residue-specific order parameters of the Ala ^{15}N amide and C- α sites were in good agreement. Moreover, values of S^2 were in the range 0.8–0.95 for nearly all amino acids in the protein. This result showed that internal motion of the SNase backbone is limited to rapid small-amplitude

motions. Exceptions to this statement are (a) highly flexible residues in the N- and C-termini which have large T_2 values, and (b) several residues in the functionally important Ω loop which have unusually small T_2 values. In the X-ray structure of SNase³² residues in the Ω loop have weak electron density and large B factors. In solution, the loop is highly flexible, as evidenced by the broad lines and missing amide signals of residues in, or adjacent to, the loop. Although the Ω loop is flexible, it has a significant role in catalysis, as constructs of SNase lacking the loop have virtually the same structure as the parent molecule, but significantly lower levels of activity.

Although the side chains of all 11 leucine (Leu) residues in SNase are in well-structured regions of the protein, the values of S^2 of the Leu methyl sites fall into two distinct classes.^{23,30} In the presence of stabilizing ligands, thymidine 3',5'-bisphosphate and Ca^{2+} , four residues have values of S^2 , approx. 0.4–0.5, that are substantially less than the values of S^2 , approx. 0.8–0.9, of six of the remaining residues. This result indicates that there is a significant range in the flexibility of the large, hydrophobic side chains in SNase. Furthermore, it was found that the flexibility of the Leu methyl groups was sensitive to ligand binding, with side chains in the neighborhood of the ligand binding sites increasing in flexibility in the absence of the ligands.

4.2 Calmodulin and Calbindin D_{9k}

Calmodulin is a 148-residue protein that couples fluctuations in Ca^{2+} concentration to cellular activity. In the crystalline state the protein has the shape of a dumbbell in which two globular domains are connected by a continuous 26-residue α -helix. However, a ^{15}N relaxation study has shown that residues in the center of this helix have small order parameters, in the 0.5–0.6 range.³³ In addition, the relaxation data showed that the N- and C-terminal globular domains tumble nearly isotropically with slightly different correlation times. These results are strong evidence that the central helix is flexible in solution, a result that structural studies of the calmodulin/M19 complex have confirmed.³⁴

Calbindin D_{9k} is a 75-residue member of the calmodulin superfamily of calcium-binding proteins, containing two calcium binding sites. A careful comparison of ^{15}N relaxation measurements³⁵ made on the apo protein, the protein with Ca^{2+} in binding site II, and the protein with ions in both sites I and II, has shown that ion binding has very small effects on amide order parameters, with the notable exception of residues in binding site II. The order parameters of these residues increase from 0.6 to 0.85 when an ion is bound in site II. In contrast, residues in site I have large order parameters, S^2 approx. 0.8–0.85, in the absence and presence of bound ions. The asymmetry in the dynamic behavior of the two Ca^{2+} binding sites may be related to the fact that site I is not a typical EF hand (Ca^{2+} -binding loop), and is being characterized by further work on protein samples, half saturated with Ca^{2+} .

4.3 Interleukins, IL-1 β , IL-4, and IL-8

High-resolution crystal and solution structures, as well as backbone amide order parameters are available³⁶ for IL-1 β , IL-4, and IL-8. Analysis of these extensive data has

shown that amide nitrogen order parameters correlate with the inverse of (a) rms deviation (rmsd) values of the amide nitrogen coordinates, derived from the NMR structures, and (b) the amide nitrogen crystallographic B factors. While the correlations show significant scatter, this is to be expected because internal motions on a timescale slower than τ_m will not usually affect S^2 but will affect the other two parameters. Furthermore, crystal contacts may hinder motions that occur in solution. In general, it was found that amide nitrogen sites, having small B factors and small rmsd values in NMR structures, are strongly correlated with amide nitrogen sites that have large values of S^2 .

4.4 Bovine Pancreatic Trypsin Inhibitor, BPTI

Bovine pancreatic trypsin inhibitor (BPTI) was one of the first proteins whose internal dynamics were characterized by NMR lineshape and relaxation studies. More recently, measurement of transverse relaxation rates using natural abundance two-dimensional ^1H – ^{13}C heteronuclear techniques has provided evidence for slow internal motions involving cysteine (Cys) 14 and Cys-38.¹⁰ A thorough investigation of this process in wild-type BPTI and in a mutant protein, BPTI(G36S), showed that the protein is an equilibrium mixture of interconverting isomers of the Cys-14–Cys-38 disulfide bond.³⁷ The rate of interconversion of the two isomers, as determined by measurements of the ^{15}N $T_{1\rho}$ of Cys-38 and of Arg-39, as a function of the spin lock field,³⁸ was in reasonable agreement with the rate of conformational exchange determined independently using two-spin-order exchange experiments and from measurements of chemical exchange line broadening. This work also demonstrates that, because of the inherent limited sensitivity of protein NMR spectra, slow dynamic processes in proteins are difficult to observe and may be more common than has been supposed.

5 SUMMARY OF ^{15}N WORK AND PROSPECTS FOR ^{13}C MEASUREMENTS

Unfortunately, space does not permit even brief individual reviews of the substantial number of other interesting proteins that have been studied using ^{15}N relaxation measurements. However, a few general comments about backbone mobility, based upon the ^{15}N relaxation work, can be made. Internal motions of the amide backbone are small in amplitude, with order parameters typically greater than 0.8 for amino acids in regions of regular secondary structure. In contrast, residues in either the terminal regions of the protein sequence or in small external loops often exhibit large amplitude, $S^2 < 0.6$, rapid internal motions, with $\tau_e \ll \tau_m$. Much slower motions, on the chemical shift timescale, are most commonly seen for large loops or segments near the protein surface, that often contain amino acid residues implicated in the function of the molecule.

While the ^{15}N studies have provided the first comprehensive view of internal dynamics of the protein backbone in solution, internal motions of protein side chains are likely to be considerably more varied and interesting. While the use of specifically ^{13}C -labeled samples is a means of studying such

motions, it would be much more efficient to use uniformly ^{13}C -labeled samples, provided that the pulse sequences can be developed that suppress effects of carbon–carbon coupling. Labeling a protein with ^{13}C at alternate carbon sites has also been proposed³⁹ to achieve this goal. Elimination of the effects of dipolar cross correlation ^{13}C relaxation measurements is also highly desirable. This has been done for glycine (Gly) C- α H_2 sites in *Escherichia coli* thioredoxin by preparing a sample labeled with 50% [$\text{U-}^2\text{H}$, 2- ^{13}C]Gly,³⁹ and recording spectra using pulse sequences that (a) select for Gly α -carbons bonded to a single proton, and (b) decouple deuterons. Deuteration also has the advantage that both carbon and proton T_2 values are significantly larger than in the protonated protein. Although it will require considerably more effort to measure relaxation parameters of protein uniformly labeled with ^{13}C than with ^{15}N , the wealth of information about protein side-chain motions that will be provided by the ^{13}C experiments should fully reward the effort required.

1 INTRODUCTION

Studies of nuclear spin relaxation processes can provide invaluable information regarding the structure and dynamics of biological macromolecules. Numerous methodologies have been proposed for the measurement and interpretation of various nuclear spin relaxation rate constants. In recent years the arsenal of tools available for NMR relaxation studies has expanded rapidly, due in part to the greater appreciation and subsequent exploitation of cross-correlation effects. The presence of cross-correlation, or relaxation interference, effects in nuclear spin relaxation processes has been recognized since the early days of NMR experimentation. One of the earliest reports on this subject was the proposal by McConnell¹ that relaxation interference effects could explain the observed dependence of multiplet linewidths on the nuclear spin quantum number in paramagnetic resonance spectra of solutions of ionic salts. Another pioneering study was that by Hubbard,^{2,3} concerning relaxation interference effects on the spin-lattice relaxation of three- and four-spin-1/2 systems. Despite these early reports, and with some notable exceptions, the prevailing view for many years seemed to be that cross-correlation effects were more of a theoretical curiosity than a practically useful

feature of nuclear spin relaxation. This sentiment was due in part to improper extrapolations of Hubbard's results to other systems.⁴ Fortunately, the rigorous theoretical treatments of cross-correlation effects by several groups, especially those of Werbelow, Grant, and Lynden-Bell,^{5–7} and the development of multi-dimensional and multiple quantum NMR methodologies in the 1970s lead to a renewed interest and solid foundation for the exploitation of cross-correlated relaxation phenomena. As a result, many important and very valuable NMR techniques that rely on the measurement and/or utilization of cross-correlation effects are now available and in common use for obtaining detailed information on the structure and dynamics of a variety of systems, including biological macromolecules.

The purpose of the present article is to provide an overview of the subject of cross-correlated nuclear spin relaxation effects (see also **Relaxation Processes: Cross Correlation & Interference Terms**, Volume 6, and **Relaxation Theory: Density Matrix Formulation**, Volume 6), focusing on those areas of particular importance in studies of the structure and dynamics of proteins, nucleic acids and other biological macromolecules. The basic concepts are emphasized, rather than providing a detailed theoretical description. Readers interested in the theoretical formalism of cross-correlated relaxation and/or a more complete presentation than is possible here are directed to an excellent and comprehensive review of cross-correlations in NMR that was published recently by Kumar et al.⁸ A number of other review and research articles are also highly recommended for those wishing to learn more about this fascinating field.^{5–14}

2 THEORY

A number of interactions can contribute to the overall relaxation behavior of a nuclear spin, including the stochastic modulation of dipole–dipole couplings, chemical shift anisotropies, and quadrupolar couplings (for spin > 1/2). Cross-correlation effects result from the interference of two such relaxation mechanisms, under the conditions that the time-dependent modulation of the two relaxation mechanisms arises from the same source, and that the tensors that describe the time-dependence of the interactions have the same rank. To put this in more formal terms, the stochastic Hamiltonian responsible for the relaxation behavior of a nuclear spin can be written as:¹⁵

$$\mathbf{H}_1(t) = \sum_m \sum_{q=-k}^k F_{mk}^q(t) \mathbf{A}_{mk}^q \quad (1)$$

in which the summation over the index m accounts for the different relaxation mechanisms, $F_{mk}^q(t)$ is a function of spatial variables that describes the effective motional behavior and $\mathbf{A}_{mk}^q$ is a tensor spin operator. The index k gives the rank of the tensor operators for the relevant interactions. The Liouville-von Neumann equation for the density operator is given by:

$$\frac{d\sigma}{dt}(t) = -i[\mathbf{H}_0, \sigma(t)] - \hat{\Gamma}(\sigma(t) - \sigma_0) \quad (2)$$

where $\mathbf{H}_0$ is the time-independent part of the nuclear spin Hamiltonian, $\sigma(t)$ is the time-dependent density operator, σ_0 is the thermal equilibrium density operator, and $\hat{\Gamma}$ is the

relaxation superoperator. If the density operator σ is expanded in terms of a set of basis spin operators $\mathbf{B}_i$, the rate constant for relaxation between the operators $\mathbf{B}_r$ and $\mathbf{B}_s$ is:

$$\begin{aligned} \Gamma_{rs} &= \frac{1}{2} \sum_m \sum_q \sum_p \{ \langle \mathbf{B}_r | [\mathbf{A}_{mkp}^{-q}, [\mathbf{A}_{mkp}^q, \mathbf{B}_s]] \rangle / \langle \mathbf{B}_r | \mathbf{B}_r \rangle \} j^q(\omega_p) \\ &\quad \cdots + \frac{1}{2} \sum_{\substack{m,n \\ m \neq n}} \sum_q \sum_p \{ \langle \mathbf{B}_r | [\mathbf{A}_{mkp}^{-q}, [\mathbf{A}_{nkp}^q, \mathbf{B}_s]] \rangle / \langle \mathbf{B}_r | \mathbf{B}_r \rangle \} j_{mn}^q(\omega_p) \\ &\quad \cdots = \sum_m \Gamma_{rs}^m + \sum_{\substack{m,n \\ m \neq n}} \Gamma_{rs}^{mn} \end{aligned} \quad (3)$$

in which the $\mathbf{A}_{mkp}^q$ are basis operators that can be summed over index p to generate the tensor operators $\mathbf{A}_{mk}^q$ appearing in equation (1), and the cross-correlation spectral density is:

$$j_{mn}^q(\omega) = \text{Re} \left\{ \int_{-\infty}^{\infty} \overline{F_{mk}^q(t)} F_{nk}^{-q}(t + \tau) \exp(-i\omega\tau) d\tau \right\} \quad (4)$$

The terms Γ_{rs}^{mn} represent the contributions to the relaxation between $\mathbf{B}_r$ and $\mathbf{B}_s$ that results from the interference or cross-correlation between the m^{th} and n^{th} relaxation mechanisms. From equation (4) it is clear that if the motional processes modulating relaxation mechanisms m and n are uncorrelated, there will be no cross-correlated relaxation involving these two mechanisms. Likewise, from equation (3) it can be seen that cross-correlated relaxation requires that the double commutator involving spin operators $\mathbf{A}_{mkp}^{-q}$ and $\mathbf{A}_{nkp}^q$ be non-zero. In applications to biomolecules, the most common relaxation interference effects arise from the three cross-correlation combinations involving the dipole–dipole (DD) and chemical shift anisotropy (CSA) relaxation mechanisms.

The concept of cross-correlated nuclear spin relaxation can be illustrated by considering a simple two spin-1/2 system, a ^{15}N – ^1H spin pair in a protein backbone, and analyzing the transverse relaxation of the ^{15}N spin.¹⁶ The relevant cross-correlation in this example is the relaxation interference between the ^{15}N chemical shift anisotropy (CSA) and the ^{15}N – ^1H dipole–dipole (DD) interactions. Figure 1 demonstrates the basic principle of CSA/DD cross-correlated relaxation in the ^{15}N – ^1H system. The case of a ^{15}N spin bonded to a ^1H spin in the $|\alpha\rangle$ state (as indicated by the upward arrow through the ^1H nucleus) is shown in Figure 1(A) and (B); in Figure 1(A) the ^{15}N – ^1H bond vector is oriented parallel to the externally applied magnetic field, whereas Figure 1(B) shows the case where the bond vector is perpendicular to the applied field. Figure 1(C) and (D) show the analogous situations where the ^1H spin is in the $|\beta\rangle$ state. The solid lines drawn to the right of the ^{15}N nuclei indicate the direction of the local magnetic field, arising from the ^1H spin, at the position of the ^{15}N spin, while the dashed lines to the left of the ^{15}N nuclei show the direction of the induced magnetic field arising from the ^{15}N CSA interaction. Relaxation of the ^{15}N spin is caused by fluctuations in the net sum of these local magnetic fields as the orientation of the bond vector is randomly modulated by motional processes. The key observation in this example is that when the ^1H spin is in the $|\alpha\rangle$ state, the local magnetic fields arising from the CSA and DD interactions have the same sign, regardless of the bond orientation, whereas these local fields have opposite signs when the ^1H spin

is in the $|\beta\rangle$ state. Constructive interference of the local magnetic fields arising from the CSA and dipolar interactions will therefore result in a broadening of the ^{15}N resonance associated with the ^1H in the $|\alpha\rangle$ state, while destructive interference of these local fields will lead to a narrowing of the ^{15}N resonance associated with the ^1H in the $|\beta\rangle$ state. This type of cross-correlated relaxation effect forms the basis of TROSY, or transverse relaxation-optimized spectroscopy (see **Transverse Relaxation-optimized NMR Spectroscopy with Biomacromolecular Structures in Solution**).

The measurement of cross-correlated relaxation rate constants is greatly facilitated by the fact that the relaxation behavior can be controlled in a substantial way via the design of the pulse sequences.¹⁷ This is quite different from the situation that exists for the measurement of auto-relaxation processes, where pulse sequence elements normally do not affect relaxation. Thus, pulse sequence design has played an essential role in allowing various cross-correlated relaxation processes to be distinguished from one another and in allowing quantitative analyses to be performed. Cross-correlated relaxation rate constants are normally measured in one of two ways. The first method is to observe changes in individual multiplet intensities after an evolution period (usually a constant-time element) during which the relaxation processes of interest have been active. The second possibility is to observe and measure the cross-correlation-induced cross-relaxation of one spin operator with another. In many cases the cross-correlated relaxation rate constants of interest are rather small, and this can present significant challenges in terms of making reliable measurements. Careful attention to experimental design can reduce some sources of uncertainty and error in cross-correlated relaxation measurements.¹⁸

Figure 1 Schematic illustration of the origin of ^{15}N chemical shift anisotropy/ ^{15}N – ^1H dipole–dipole cross-correlation effects on the relaxation of the ^{15}N spin. Arrows through the ^1H nuclei indicate the ^1H spin state $|\alpha\rangle$ (up arrow) or $|\beta\rangle$ (down arrow). Solid arrows adjacent to the ^{15}N nuclei indicate the direction of the local ^1H dipolar magnetic field at the site of the ^{15}N spin, while the dashed arrows indicate the direction of the induced magnetic field from the ^{15}N chemical shift interaction. In (A) and (C) the ^{15}N – ^1H bond vector is parallel to the applied external field, while in (B) and (D) the bond vector is in the perpendicular orientation

Cross-correlation effects in nuclear spin relaxation can be exploited for a number of useful purposes in studies of biomolecules, including sensitivity and/or resolution enhancement, dynamics studies, and measurement of structural constraints. Cross-correlation contributions to relaxation can also be an undesirable feature in dynamics studies that are based on the measurement of auto-relaxation rate constants, and thus it has been necessary to devise various techniques for eliminating specific, cross-correlation-induced cross-relaxation pathways. The following sections describe examples of both the exploitation and elimination of cross-correlation effects that have been found to be of particular relevance in studies of biological macromolecules.

3 SENSITIVITY AND RESOLUTION ENHANCEMENT VIA CROSS-CORRELATION EFFECTS

3.1 TROSY

One of the most exciting and important developments in recent years in the field of solution-state NMR studies of biomolecules has been the introduction of methodologies for sensitivity and/or resolution enhancement that are based on the exploitation of cross-correlation effects. These enhancements have their origin in the differential relaxation rates of multiplet components in the presence of relaxation interference between DD and CSA interactions. Griffey and Redfield anticipated the potential advantages of DD/CSA cross-correlation, as evidenced by their statement that "In certain cases higher resolution and/or sensitivity might be achieved by operating without decoupling, perhaps using an INEPT or double-INEPT sequence".¹⁹ Their belief was validated ten years later when Pervushin and coworkers²⁰ reported the development of an experimental scheme for transverse relaxation-optimized spectroscopy (TROSY). The TROSY methodology is the subject of another article in this volume, and so only a very brief discussion of the basic principles is presented here.

One of the most important and widely used NMR techniques for studies of biomolecules is the 2D HSQC experiment,¹⁵ which provides correlation information for heteronuclear spin pairs such as ^1H - ^{15}N or ^1H - ^{13}C . The HSQC-type pulse scheme is an integral component in most heteronuclear, multi-dimensional NMR experiments. The sensitivity and resolution of HSQC-based experiments is dependent on the transverse relaxation rates of the spins actively involved in the coherence transfer pathway. As the molecular weight of the system under study increases, so do the transverse relaxation rate constants, and thus the sensitivity and resolution of the HSQC spectra are degraded. In the presence of significant dipole-dipole/CSA relaxation interference, the linewidths of individual spin multiplet components can be quite different. The spin decoupling normally performed during an HSQC-type experiment causes an averaging of the transverse relaxation rates of the multiplet components. However, by carefully avoiding this mixing of spin states, it is possible to take advantage of the line-narrowing of one of the multiplet components that arises due to destructive interference of the dipole-dipole and CSA interactions.¹⁴ This forms the basis for the TROSY scheme, as was illustrated in Figure 1. In the first application reported by Pervushin et al.,²⁰ the TROSY scheme

was incorporated into a 2D ^1H - ^{15}N HSQC experiment. The pulse sequence was designed to select only one of the four multiplet components that would normally be observed for a ^1H - ^{15}N spin pair correlation in an uncoupled 2D HSQC spectrum. Selecting the component with the smallest ^{15}N and ^1H linewidths can lead to significant improvements in sensitivity and/or resolution, under favorable conditions. Heading the list of required conditions of course is that there be a significant dipole-dipole/CSA cross-correlation effect. Thus, the TROSY scheme is most effective at ultra-high magnetic field strengths, due to the field dependence of the CSA interaction, and for heteronuclei with large chemical shift anisotropies, such as ^{15}N or aromatic ^{13}C spins. A number of other factors also affect whether the TROSY scheme will provide useful sensitivity and/or resolution enhancements. Other sources of relaxation, such as dipolar interactions with remote protons, will tend to mask the line narrowing from the DD/CSA interference, as will exchange contributions to the linewidths. Thus, TROSY-based schemes are most useful for large molecular systems that are highly deuterated and not subject to conformational exchange broadening. Even under such conditions, the maximal advantage theoretically possible for a TROSY-based pulse sequence is usually not reached, due to different data acquisition and processing parameters for TROSY and non-TROSY experiments. For example, the advantage of reduced transverse relaxation rates in the ^{15}N evolution period of a TROSY-based HSQC is most useful if relatively long evolution periods are required; such is the case for experiments used to measure small coupling constants. Implementation of the TROSY scheme is also of particular value in constant-time periods in various multi-pulse sequences to minimize relaxation-associated loss of signal intensity.

In practical applications, the TROSY scheme has been extremely useful for studies of deuterated molecules or complexes, especially those that are in excess of 50 kDa in size. The TROSY scheme has been incorporated into a large number of the standard triple resonance experiments employed for resonance assignment as well as other pulse sequences, such as those used to measure small scalar couplings across hydrogen bonds (see **Polarization Transfer Experiments via Scalar Coupling in Liquids**, Volume 6).

The TROSY scheme, as it was originally proposed, was based on the exploitation of relaxation interference between dipole-dipole and CSA interactions to achieve line narrowing of single quantum coherences. Griffey and Redfield¹⁹ pointed out that line-narrowing could also be achieved for zero-quantum (ZQ) coherences, utilizing relaxation interference of the CSA interactions of the two spins actively involved in the ZQ coherence. Pervushin and coworkers²¹ have developed a modified TROSY scheme to take advantage of this ZQ line-narrowing via the cross-correlation of ^{15}N and ^1H CSA interactions for ^{15}N - ^1H spin pairs. They have also incorporated this ZQ-TROSY scheme into a novel 3D ^{15}N -separated ^1H - ^1H NOESY experiment. The three main features/advantages of this so-called 3D NOESY- ^{15}N , ^1H -ZQ-TROSY experiment are: (1) the ^{15}N CSA/ ^1H CSA cross-correlation is used to reduce transverse relaxation during the ^{15}N evolution time; (2) line-narrowing is achieved in all three frequency dimensions; and (3) substantial suppression of the diagonal peaks is achieved, thereby facilitating the observation of NOESY cross-peaks that lie very close to the diagonal.

3.2 CRINEPT

Most multi-dimensional experiments applied to biomolecules employ polarization/coherence transfer steps to transfer magnetization from one nuclear species to another; in some cases this is done solely for sensitivity enhancement, and in others it is done to implement a desired coherence transfer pathway. The coherence transfer between two spins I and S normally involves the evolution of magnetization under the scalar coupling Hamiltonian according to (assuming a pulse-interrupted free precession period)

$$I_x \xrightarrow{H_J} I_x \cos(\pi J_{IS}\tau) + 2I_y S_z \sin(\pi J_{IS}\tau) \quad (5)$$

where J_{IS} is the scalar coupling between spins I and S . Coherence is transferred from I to S by the application of 90° rf pulses to the I and S spins to convert the second term above from anti-phase I spin magnetization to anti-phase S spin magnetization. The 90° rf pulses are applied at a time τ that is chosen to optimize the efficiency of the transfer; in the absence of relaxation, exchange effects, and remote couplings to the I spin, the optimal value of τ would be $1/(2J_{IS})$. However, in the presence of significant I spin relaxation and/or exchange broadening of the I spin, the coherence transfer process is adversely affected and τ will have to be reduced in order to obtain the maximum transfer allowed by the experimental conditions. The loss of magnetization due to relaxation during the scalar coupling evolution period becomes increasingly significant as the size, and thus the rotational correlation time, of the system increases.

Another possibility exists for achieving polarization/coherence transfer between a heteronuclear spin pair. Dalvit²² and Brüschweiler and Ernst²³ have demonstrated the possibility of employing DD/CSA cross-correlation effects to obtain a coherence transfer of the type

$$I_x \xrightarrow{\Gamma_{\text{DD, CSA}}} 2I_x S_z \quad (6)$$

In this case the relevant process is the cross-correlation of the I spin CSA and the dipolar interaction between the I and S spins. Coherence can then be transferred from the I spin to the S spin via the anti-phase term by application of 90° rf pulses to both I and S spins. Riek and coworkers²⁴ have coined the term CRIPT (cross relaxation-induced polarization transfer) for this process, and have discussed the sensitivity advantages achievable, relative to scalar coupling-induced coherence transfer, in applications to very large molecules. They have also developed experimental procedures for utilizing both scalar coupling-induced and cross-correlation-induced coherence transfer pathways in a methodology they have named CRINEPT. Maximum sensitivity enhancements in appropriate applications are obtained by also including the TROSY scheme in the CRINEPT pulse sequences.²⁵

3.3 CSA Tensor Characterization via Cross-Correlation Effects

Accurate knowledge of CSA tensors is important for interpreting the results of many NMR experiments in order to obtain structural and motional parameters. Information concerning the magnitude and orientation of CSA tensors

has most commonly been obtained from solid-state NMR studies of model compounds. However, experimental studies have demonstrated that CSA tensors are very sensitive to the local environment of a nucleus in a biomolecule, and thus the applicability of tensor parameters from small model compounds is limited. Progress has been made in the use of quantum-chemical calculations to obtain CSA tensor parameters,²⁶ but there clearly is still a great need to have procedures for experimentally measuring such parameters directly from the systems of interest. Such measurements are potentially a valuable source of structure and dynamics information.

Several groups have demonstrated that site-specific, quantitative information on ^1H , ^{13}C and ^{15}N chemical shift anisotropies can be obtained for these nuclei in biomolecules from the measurement of dipole–dipole/CSA relaxation interference effects.⁸ Several related procedures have been proposed for obtaining CSA information from DD/CSA relaxation interference measurements. For a heteronuclear two spin (I , S) system, DD/CSA transverse cross-correlation rate constants can be obtained either from measurements of the differential relaxation of the individual doublet components or from measurements of the $I_x \rightarrow 2I_x S_z$ coherence transfer process. The methodology described by Kroenke and coworkers²⁷ also involves measurement of the longitudinal cross-correlation rate constants via the $I_z \rightarrow 2I_z S_z$ polarization transfer process. Fushman and coworkers²⁸ demonstrated that the magnitudes and the orientation of a CSA tensor (^{15}N in their study) can be obtained from magnetic field-dependent measurements of the ratio η/R_2 , where η is the transverse DD/CSA cross-correlation rate constant and R_2 is the heteronuclear transverse relaxation rate constant. Pang and Zuiderweg²⁹ have proposed an elegant procedure for determining the protein backbone $^{13}\text{C}'$ carbonyl CSA tensor that involves measuring the relaxation interference between the $^{13}\text{C}'$ CSA transverse relaxation and three different dipole–dipole relaxation terms: $^{13}\text{C}'\text{--}^{13}\text{C}^\alpha$, $^{13}\text{C}'\text{--}^{15}\text{N}$, and $^{13}\text{C}'\text{--}^1\text{H}^\text{N}$.

4 MEASUREMENT OF ANGLES BETWEEN BOND VECTORS

Due to the dependence of cross-correlated relaxation effects on the relative orientation of the interaction tensors involved, the measurement of such effects can provide valuable structural information in studies of biomolecules. Considering CSA and dipolar interactions, cross-correlated relaxation can arise from the CSA of two different spins, from the CSA of spin i and the dipolar interaction between spins j and k [DD(jk)], from the CSA of spin j or k and the dipolar interaction between spins j and k affecting the relaxation of spin i , and from two pairs of dipolar interactions DD(ij) and DD(kl) with no common spin between them. In such cases the cross-correlation effects depend on the relative orientation of the relevant interaction tensors but not explicitly on distances. These types of cross-correlations are termed ‘remote’,³⁰ since the relaxation interference does not depend explicitly on the distance of other spins from the spin or spins of interest. For example, the CSA/CSA cross-correlation involving spins i and j does not depend explicitly on the distance between i and j . Likewise, the DD/DD cross-correlation between spin pairs i , j and k , l depends on r_{ij} (the distance between spins i and j) and

r_{kl} inter-nuclear distances but not explicitly on the distances between the spin pairs, i.e., the r_{ik} , r_{il} , r_{jk} or r_{jl} distances.

Reif and coworkers³¹ introduced a strategy which utilizes remote cross-correlation effects to measure the relative orientation of bond angles; a major advantage of this strategy is the fact that there is no requirement to establish a parameterized Karplus-type relationship, as there is when scalar couplings are used to measure torsion angles. Another advantage is the fact that the cross-correlated relaxation is not limited to the analysis of local geometry, since there is no explicit distance dependence. In principle, the relative orientation of arbitrary interaction tensors within one molecule, or even between two molecules, can be measured as long as a correlation between these two can be established.¹⁷

An approach that has proven to be very effective for the measurement of remote cross-correlation effects is to examine the relaxation behavior of double and zero quantum coherences created between nuclei affected by the interactions of interest. In the strategy proposed by Reif et al., double quantum coherence is created involving the $^{13}\text{C}^\alpha$ nucleus of amino acid residue i and the backbone ^{15}N nucleus of residue $i + 1$ in a protein, and the effects of relaxation interference between the $^{13}\text{C}^\alpha\text{--}^1\text{H}^\alpha$ (residue i) and the $^{15}\text{N}\text{--}^1\text{H}^\text{N}$ (residue $i + 1$) dipolar interactions on the $^{13}\text{C}^\alpha\text{--}^{15}\text{N}$ double quantum coherence is probed. The cross-correlation effects are manifested in the differential relaxation rates of the four double quantum transitions. These rates can be determined either from the linewidths of the double quantum signals or from resonance intensities measured from a constant-time NMR experiment. For practical reasons the latter approach is normally easier to accomplish. Intensity ratios provide a measure of the desired cross-correlation relaxation rate constants. In turn, these rate constants can then be used to determine the relative orientation of the interaction tensors.¹⁴ For the example described here, and assuming a macromolecule that tumbles slowly in solution, the cross-correlated dipolar relaxation depends on the angle θ between the $^{13}\text{C}^\alpha\text{--}^1\text{H}^\alpha$ (residue i) and $^{15}\text{N}\text{--}^1\text{H}^\text{N}$ (residue $i + 1$) bonds according to

$$\Gamma = \frac{\gamma_H \gamma_N}{(r_{NH})^3} \frac{\gamma_H \gamma_C}{(r_{CH})^3} \left(\frac{\hbar \mu_o}{4\pi} \right)^2 \frac{2}{5} (3 \cos^2 \theta - 1) \tau_c \quad (7)$$

The γ_H , γ_N and γ_C are the magnetogyric ratios of the ^1H , ^{15}N and ^{13}C nuclei, respectively, r_{NH} and r_{CH} are the $^{15}\text{N}\text{--}^1\text{H}^\text{N}$ and $^{13}\text{C}^\alpha\text{--}^1\text{H}^\alpha$ inter-nuclear distances, respectively, τ_c is the rotational correlation time of the molecule, and $\hbar$ and μ_o are natural constants. This expression does not take fast internal motion or anisotropic reorientation of the molecule into account. Due to the planarity of the peptide bond, the angle θ can be directly related to the dihedral angle ψ , and thus the dipole–dipole cross-correlation measurement provides information on the allowed values of ψ . Such information can provide important new structural constraints in the structure determination of proteins, due to the fact that the dihedral angle ψ is difficult to assess by other experimental means.

Since the pioneering work of Reif et al. was first reported, additional and/or improved schemes for using cross-correlation effects to assess ϕ and ψ dihedral angles in proteins and sugar puckers in nucleic acids have been proposed by several groups (see for example Kloiber and Konrat³² and references cited therein). Almost all of these schemes have been based on the measurement of DD/DD and/or DD/CSA cross-correlation

effects. However, Skrynnikov and coworkers³³ have proposed a technique for measuring CSA cross-correlated relaxation between pairs of carbonyl spins in proteins, and have demonstrated that in the case where the carbonyl spins reside on successive residues, information about the intervening (ϕ , ψ) backbone dihedral angles is obtained. They also demonstrated the possibility of observing CSA/CSA cross-correlated relaxation between carbonyl spins residing on two peptide planes linked via a hydrogen bond, which can provide information about the relative orientation of these planes. With the availability of dihedral angle information, especially for the ψ angles, from various cross-correlated relaxation measurements, it has become possible to use such structural constraints in NMR protein structure calculations. Refinement methods that have been modified to incorporate cross-correlation-based structural constraints can be used to significantly improve the quality of NMR structures and are applicable to larger proteins.³⁴

5 STUDIES OF MOLECULAR DYNAMICS VIA CROSS-CORRELATED RELAXATION EFFECTS

The measurement of nuclear spin relaxation rate constants provides valuable information on motional processes occurring within biomolecules. Experiments for measuring auto-correlated relaxation rate constants for ^1H , ^{13}C , ^{15}N and ^2H are in widespread use, particularly for characterizations of the backbone dynamics and the rotational diffusion tensor of proteins and their complexes.¹¹ Building upon this base, there is growing interest in obtaining more detailed information on conformational dynamics within proteins. Two areas of focus are the development of more realistic models of the local motions of peptide planes in proteins and quantitative measurements of side chain dynamics. Cross-correlated relaxation experiments are proving to be particularly useful for studying the motional properties of structural elements that have a fixed geometry, such as peptide planes and CH_2 , CH_3 and NH_2 groups. The motions of such moieties within proteins and similar elements within other biomolecules are expected in general to be anisotropic. Experimental NMR studies of such anisotropic motions are greatly facilitated by exploiting the sensitivity of cross-correlated relaxation rates to the direction of motion. Cross-correlated relaxation measurements are complementary to the standard auto-correlated relaxation experiments in several ways. Cross-correlation rate constants are not, or only little, affected by conformational or chemical exchange processes (see **Chemical Exchange Effects in Biological Macromolecules**), spin-rotation relaxation, or relaxation by paramagnetic oxygen;³⁵ such contributions can complicate the interpretation of dipolar or CSA auto-relaxation data. An additional advantage is that transverse cross-correlation effects are generally confined to subsystems containing two, three or four spins, with outside spins having little effect. On the other hand, a potential complication in the use of cross-correlation effects involving CSA interactions is that independent knowledge of the CSA tensor parameters is necessary in order to separate out the motional contributions to the cross-correlated relaxation processes. Information from other sources, such as solid-state NMR, molecular dynamics simulations, and CSA quantum chemical calculations, can be employed for characterizing the necessary CSA tensor parameters.^{26,35}

A thorough description of the theory and application of cross-correlated relaxation measurements for studies of motional processes in biomolecules is beyond the scope of this article. The interested reader is directed to several excellent review articles that have appeared recently.^{8–11} Instead, a very limited survey of some of the most promising uses of cross-correlation effects in biomolecular dynamics studies is presented here.

5.1 Dipole–Dipole/Dipole–Dipole Cross-Correlation Measurements

The cross-correlated relaxation measurements most commonly employed in biomolecular NMR studies involve dipole–dipole/dipole–dipole (DD/DD) and DD/CSA interactions. The measurement of DD/DD cross-correlated relaxation has the advantage that no assumptions generally need to be made about the interaction tensors, since they involve known physical constants such as the bond lengths, the orientation of the principal axis of the dipolar tensor is usually known, and the dipolar tensor is axially symmetric. There has been a long history to the use of DD/DD cross-correlated relaxation effects for characterizing molecular motions. Much of the work has focussed on the examination of relaxation effects for proton-coupled ^{13}C spins, especially for AX_2 and AX_3 groups.^{7,8,10} For the ^{13}C multiplet spectra of methylene and methyl groups, the central and outer components of the multiplet exhibit different relaxation behavior as a result of DD/DD cross-correlation.¹⁰ Differences in the high field relaxation behavior of the outer lines of the ^{13}C multiplet result from DD/CSA cross-correlation. Building upon earlier work of their own and that of other groups such as Grant, Werbelow and Bodenhausen, Daragan and Mayo have championed the use of DD/DD cross-correlated relaxation measurements for obtaining information on motional processes in biomolecules.^{10,11}

A particularly useful method for measuring DD/DD cross-correlated relaxation in heteronuclear spin systems is to monitor the cross-relaxation process $S_z \rightarrow 4S_z I_{1z} I_{2z}$; this technique has been referred to as “SIIS cross relaxation”.³⁶ This cross-relaxation process can occur only when the two heteronuclear dipolar interactions SI_1 and SI_2 are modulated in a correlated manner by the random process that causes relaxation. The SIIS-type of experiment is particularly useful for characterizing the motion of CH_2 groups about χ dihedral angles in the side chains of proteins, since the relative orientation of the two interacting dipoles is known. Measurements of scalar coupling constants can provide information concerning the relative populations of χ rotamers, but provides no information on the rate constants for the bond rotations. By measuring the cross-relaxation behavior between the S_z polarization and the three-spin order $4S_z I_{1z} I_{2z}$, Ernst and Ernst³⁶ demonstrated that it is possible to distinguish between equally populated three-site jump or unrestricted rotational diffusion models on the one hand and two-site or restricted rotational diffusion models on the other hand; it is often possible to make this judgement based just on the sign of the cross-relaxation peaks. The SIIS cross-relaxation process is typically measured by creating either the S_z polarization or the three-spin order $4S_z I_{1z} I_{2z}$, and then detecting the cross-relaxation partner. Due to the slow tumbling of large molecules, there is some advantage to performing the experiment in the so-called tilted rotating frame, as in the related T-ROESY experiment.³⁷ The reason for this

is that in the laboratory frame the cross-relaxation process depends only on the spectral density function at the Larmor frequency ω_{os} , which tends towards zero as the tumbling slows. A dependence on $J(0)$ is introduced by performing the experiment in the tilted rotating frame. Yang and coworkers³⁸ have proposed an alternative method, using a triple resonance pulse scheme, for measuring cross-correlated dipole–dipole spin relaxation in proteins. Their experiment records $^{13}\text{C}^\beta$ multiplet component intensities in one of the three dimensions, and the cross-correlation relaxation rate constant for the interaction between the two ^{13}C β -methylene ^{13}C – ^1H dipoles is obtained by taking the appropriate ratio of multiplet component intensities. Kay’s group, among others, has elegantly demonstrated the usefulness of DD/DD cross-correlation measurements for assessing side-chain dynamics in folded and unfolded proteins and for selecting appropriate motional models.^{10,38,39}

A number of DD/DD cross-correlations exist among the various nuclei that form the backbone of a protein, and in principle measurements of the associated cross-correlated relaxation rate constants can provide information about the dynamics of peptide planes. Carlomagno and coworkers⁴⁰ proposed a scheme for measuring the sum of the $^{13}\text{C}'$ – $^{13}\text{C}^\alpha$ / ^{15}N – $^1\text{H}^\text{N}$ and $^{13}\text{C}'$ – $^1\text{H}^\text{N}$ / ^{15}N – $^{13}\text{C}^\alpha$ DD/DD cross-correlated relaxation rate constants by analyzing the influence of these processes on ^{15}N – $^{13}\text{C}'$ double and zero quantum coherences. The same experiment gives access to the cross-correlated relaxation rate constants between the $^{13}\text{C}'$ CSA and the ^{15}N – $^1\text{H}^\text{N}$ or $^{13}\text{C}'$ – $^{13}\text{C}^\alpha$ dipoles. The rate constants are very small for small proteins, and thus are difficult to interpret quantitatively. However, the rate constants are expected to increase for larger molecules, which would allow a more rigorous, quantitative analysis. Nevertheless, even a qualitative analysis of the DD/DD cross-correlation data can be helpful in identifying anisotropic motions of peptide planes. Another possible DD/DD cross-correlation involving protein backbone nuclei is the $^1\text{H}^\text{N}$ – ^{15}N / $^1\text{H}^\text{N}$ – $^{13}\text{C}'$ dipole–dipole interaction, which has been examined by Zuiderweg’s group.⁴¹

5.2 Dipole–Dipole/CSA Cross-Correlation Measurements

The measurement of dipole–dipole/CSA cross-correlation effects has proven to be quite valuable for studying motional processes in biomolecules. Such experiments have found important applications in characterizing motional processes occurring on both fast timescales (picosecond–nanosecond) and slower timescales (microsecond–millisecond).

Tjandra and coworkers⁴² demonstrated the possibility of measuring ^{15}N – ^1H dipolar/ ^{15}N CSA relaxation interference effects to obtain approximate values of the generalized order parameter S^2 that is frequently used to characterize the motional properties of bond vectors such as the backbone $^1\text{H}^\text{N}$ – ^{15}N amide group in proteins. They proposed a straightforward experiment for monitoring the cross-relaxation between in-phase ^{15}N coherence, S_x (or S_y), and anti-phase coherence, $2I_z S_x$ (or $2I_z S_y$), and measuring the corresponding cross-correlation rate constant η_{xy} . The theoretical expression for this transverse cross-correlation rate constant is^{42,43}

$$\eta_{xy} = -\frac{\sqrt{3}}{6}cdP_2(\cos\beta)[4J(0) + 3J(\omega_N)] \quad (8)$$

in which $d = (\mu_0 h \gamma_H \gamma_N) / (8\pi^2 r_{NH}^3)$, $c = \gamma_N B_0 \Delta\sigma / \sqrt{3}$, μ_0 is the permeability of free space, h is Planck's constant, γ_H and γ_N are the magnetogyric ratios for ^1H and ^{15}N , respectively, r_{NH} is the distance between the two nuclei, B_0 is the static magnetic field strength, $\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp}$, the principal components of the ^{15}N CSA tensor are $\sigma_{\parallel}$ and $\sigma_{\perp}$, $P_2(x) = (3x^2 - 1)/2$, β is the angle between the symmetry axis of the ^{15}N CSA tensor and the ^{15}N – ^1H bond vector, and $J(\omega)$ is the spectral density function. Since the cross-correlation rate constant η_{xy} is proportional to the generalized order parameter S^2 (through the dependence on the spectral density function), measurements of η_{xy} yield information on the amplitude of rapid internal motions within a biomolecule. A major advantage of utilizing measurements of η_{xy} is the fact that this cross-correlation process is not affected by line broadening caused by slow conformational exchange,^{23,42} and thus the interpretation of the data is greatly simplified in that regard. A disadvantage of the method, however, is that variation in S^2 and $\Delta\sigma$ cannot be distinguished from each other in terms of their effect on η_{xy} . Thus, one must be cautious when interpreting changes in η_{xy} , due to the uncertainties there may be in knowledge of $\Delta\sigma$. On the other hand, if the generalized order parameter S^2 has been determined independently, measurement of η_{xy} can provide information on $\Delta\sigma$.⁴²

Dipole–dipole/CSA cross-correlation can cause not only the transverse cross-relaxation process described above but also the longitudinal cross-relaxation process between a single spin order S_z and two-spin order $2I_z S_z$, characterized by a rate constant η_z . The theoretical expression for η_z is⁴³

$$\eta_z = -\sqrt{3}cdP_2(\cos\beta)J(\omega_N) \quad (9)$$

with the various symbols having the same definitions as above in the expression for η_{xy} . Kroenke and coworkers⁴³ have developed a method for distinguishing the contributions of chemical exchange from the contributions due to anisotropic rotational diffusion in ^{15}N spin relaxation studies by measuring both the longitudinal and transverse relaxation interference between the ^1H – ^{15}N dipolar and ^{15}N CSA interactions. Accurate assessment of chemical exchange contributions to transverse relaxation rate constants (R_2) is critical for a proper interpretation of both model-free and spectral density mapping results. If a biomolecule is regarded as a spherical top that rotates isotropically in solution, then the trimmed mean value of the ratio R_2/R_1 (R_1 is the spin-lattice relaxation rate constant) provides an estimate of the isotropic rotational correlation time of the molecule. Atomic sites subject to chemical or conformational exchange have significantly increased R_2/R_1 ratios. A serious complication arises if the rotational diffusion of the molecule is not isotropic. If rotational diffusion anisotropy is significant, increases in the values of R_2/R_1 for a given nucleus can result from particular orientations of the symmetry axis of the dipolar or CSA tensor in the principal axis frame of the diffusion tensor. These increases can be interpreted mistakenly as evidence of conformational exchange. At the same time, real chemical exchange contributions to R_2 interfere with measurements of the rotational diffusion anisotropy by systematically increasing the R_2/R_1 ratio for the affected nuclei. In practice, sites with large R_2/R_1 ratios are excluded from analysis, which reduces the available data and risks exclusion of data important for accurate assessment of rotational diffusion anisotropy.

The basis for the methodology proposed by Kroenke et al.⁴³ is the fact that both η_{xy} and η_z are independent of chemical exchange and that the η_{xy}/η_z ratio is, to a good approximation, independent of the principal values and orientations of the CSA tensor, unlike the η_{xy} and η_z values separately. As a result, the η_{xy}/η_z ratio is sensitive only to internal and overall motions that contribute to dipolar and CSA relaxation mechanisms. The dependence of the η_{xy}/η_z ratio on the orientation of the ^1H – ^{15}N bond vector in a molecular reference frame provides a robust method of determining the rotational diffusion tensor. In addition, comparison of the η_{xy}/η_z ratios to the R_2/R_1 ratios permits unequivocal identification of nuclei that are subject to chemical exchange processes, without the need for multi-field and/or rotating-frame relaxation experiments. The methodology for measuring η_z is straightforward.⁴³ A potential complication in the measurement of η_z is the competing cross-relaxation of the $2I_z S_z$ two-spin order ($I \equiv ^1\text{H}$) with surrounding protons. This problem can be minimized through the use of deuteration or by more complex experimental schemes.^{44,45}

Cross-correlated relaxation measurements are proving to be a rich source of information for characterizing the backbone dynamics of proteins. Such motions have commonly been studied through the use of ^{15}N , $^{13}\text{C}^\alpha$ and, more recently, $^{13}\text{C}'$ carbonyl auto-correlated relaxation experiments. Several groups have demonstrated that the measurement of various relaxation interference effects, many involving the cross-correlation of dipole–dipole and CSA interactions, can provide useful insights concerning the locally anisotropic motions of peptide planes and complement the information obtained from auto-correlated relaxation experiments. A large number of relaxation interference effects are possible among the group of spin-1/2 nuclei in the protein backbone ($^{13}\text{C}'$, ^{15}N , $^1\text{H}^\text{N}$, $^{13}\text{C}^\alpha$, $^1\text{H}^\alpha$), and many have already been exploited. Only some of the possibilities that have been demonstrated are discussed here.

Zuiderweg's group has reported that there is a poor correlation between the generalized order parameters of the C' – C^α and the $^1\text{H}^\text{N}$ – ^{15}N bond vectors, as determined from auto-correlated relaxation studies.⁴⁶ They interpreted the lack of correlation as evidence of local or semi-local anisotropic motion of the peptide planes. To further their studies, they developed a new experiment to measure the relaxation interference between the carbonyl (C') CSA and the $^{13}\text{C}'$ – $^{13}\text{C}^\alpha$ dipole–dipole relaxation interactions. The availability of such additional experimental data that reports on anisotropic motion is of great value for modeling such motions.^{10,11,47} The Zuiderweg group has also developed a novel scheme for measuring transverse $^{13}\text{C}'$ – $^1\text{H}^\text{N}$ dipole–dipole/ $^{13}\text{C}'$ CSA cross-correlated relaxation rates, using an E.COSY-type triple resonance experiment.⁴⁸ The advantage of this method for measuring the cross-correlation effects is that it by-passes the usual requirement for having a resolvable scalar coupling between, in this case, the $^{13}\text{C}'$ and $^1\text{H}^\text{N}$ nuclei.

Brutscher and coworkers⁴⁹ devised a general scheme to use zero-quantum/double-quantum (ZQ/DQ) NMR experiments to measure various dipole–dipole/CSA cross-correlation rate constants. They demonstrated their methodology for the three-spin system consisting of the $^1\text{H}^\text{N}$, ^{15}N and $^{13}\text{C}'$ nuclei of the peptide plane in proteins. The dipole–dipole/CSA relaxation interference effects on the zero- and double-quantum coherences formed between the ^{15}N and $^{13}\text{C}'$ spins are manifested as differential relaxation in the two components of the ^{15}N – $^1\text{H}^\text{N}$ doublet. The measured relaxation rate constants include both

local and remote cross-correlation effects. There is a distinct dependence of the local and remote cross-correlation effects on internal anisotropic reorientational fluctuations of the peptide plane, providing the possibility of using such information to obtain a better understanding of local motions within a protein backbone.

5.3 CSA/CSA Cross-Correlation Measurements

Although the measurement of CSA/CSA cross-correlation effects has not yet attracted as much attention as DD/DD or DD/CSA cross-correlation measurements, the CSA/CSA-based experiments complement the other methods and can also provide valuable information for characterizing motional anisotropy within biomolecules. Vold and Vold¹² anticipated the possibility of observing CSA/CSA relaxation interference effects, which other groups subsequently have verified and elaborated upon.^{8,11} In terms of applications to biomolecules, Pellecchia and coworkers⁴¹ have demonstrated the potential usefulness of measuring the cross-correlation effects between the CSAs of the backbone amide ^{15}N and carbonyl $^{13}\text{C}'$ nuclei in proteins. Their measurement scheme is based upon the differential relaxation of double- and zero-quantum coherences formed between the backbone ^{15}N and carbonyl $^{13}\text{C}'$ spins. As it turns out, their experiment also permits the measurement of the cross-correlation between $^1\text{H}^{\text{N}}\text{--}^{15}\text{N}$ and $^1\text{H}^{\text{N}}\text{--}^{13}\text{C}'$ dipole–dipole interactions. The ^{15}N CSA tensor is, to a good approximation, axially symmetric, which simplifies the theoretical treatment. However, the $^{13}\text{C}'$ tensor is not axially symmetric. However, it is possible to decompose the $^{13}\text{C}'$ CSA tensor into two orthogonal axially symmetric tensors and separately consider the contributions of each.¹¹ Interpretation of CSA/CSA cross-correlated relaxation effects is challenging since observed variations, as reported by Pellecchia et al., can depend on local internal anisotropic motion and variations of tensor parameters and of angles between tensors. However, even though much work is still required in developing a robust procedure for interpreting CSA/CSA relaxation interference effects in biomolecules, such measurements will clearly be useful in characterizing internal motional anisotropies such as that for individual peptide planes. Such studies will be greatly facilitated by developments in the understanding of structural and motional effects on CSA tensor parameters.

6 CROSS-CORRELATION EFFECTS IN PARAMAGNETIC SYSTEMS

The presence of cross-correlation effects in paramagnetic systems has been exploited for a number of useful purposes.⁸ The dipolar interaction between a nucleus and the static electron magnetic moment results in the so-called Curie spin relaxation (CSR). A theoretical analysis demonstrates that, for example, the cross-correlation between the ^1H -Curie spin and $^1\text{H}\text{--}^{15}\text{N}$ dipolar interactions is formally identical to $^1\text{H}\text{--}^{15}\text{N}$ dipolar/ ^1H CSA cross-correlated relaxation. Boissbouvier and coworkers⁵⁰ have demonstrated that the measurement of $^1\text{H}\text{--}^{15}\text{N}$ dipole–dipole/ ^1H CSR cross-correlated relaxation rate constants can provide valuable, long-range structural constraints in NMR studies of paramagnetic molecules, due to the dependence of the rate constant on the distance between the amide proton and the electron spin and on the angle defined

by the triangle $^{15}\text{N}\text{--}^1\text{H}\text{--}\text{S}$ (S is the electron spin). Madhu and coworkers⁵¹ demonstrated that in addition to providing geometric constraints for structure refinement, the presence of cross-correlated relaxation involving the Curie spin relaxation and inter-nuclear dipolar relaxation mechanisms can also permit TROSY-type schemes to be used to obtain sensitivity and/or resolution enhancements. In this case, the enhancements can occur for any of the four components of a 2D $^1\text{H}\text{--}^{15}\text{N}$ multiplet, in contrast to the case for diamagnetic proteins and dipole–dipole/CSA cross-correlations.^{8,51} Another important consequence of cross-correlation effects in paramagnetic systems is the possibility of observing ‘relaxation-allowed’ coherence transfer between two nuclei.^{8,52}

7 CHARACTERIZATION OF HYDROGEN BOND LENGTHS

Hydrogen bond formation is an essential mechanism for the stabilization of biomolecular structures, and thus the development of experimental methods capable of directly detecting the presence of hydrogen bonds is quite valuable. Riek⁵³ has demonstrated that hydrogen bond lengths can be characterized by the measurement of DD/CSA cross-correlated relaxation involving the ^1H CSA and the dipole–dipole couplings of the ^1H to its hydrogen bond acceptor ^{15}N and to its hydrogen bond donor ^{15}N . The ratio of these two cross-correlation rate constants is dependent on the hydrogen bond length and on the generalized order parameter of the dipole–dipole $^1\text{H}\text{--}^{15}\text{N}$ vectors. Although the distance and motional contributions cannot be distinguished in this experiment, qualitative information is obtained concerning the characteristics of the hydrogen bond.

8 RELAXATION-INDUCED VIOLATIONS OF COHERENCE TRANSFER SELECTION RULES IN MULTIPLE QUANTUM NMR SPECTROSCOPY

Homonuclear multiple quantum and multiple quantum-filtered spectroscopy can be quite useful for resonance assignment in NMR studies of biomolecules.^{54,55} The interpretation of multiple quantum and multiple quantum-filtered spectra is greatly assisted by the use of the coherence transfer selection rules given by Braunschweiler and coworkers,⁵⁶ which indicate the conditions required for transfer of multiple quantum coherence to observable single quantum transitions. While the predictions made based on these selection rules generally agree very well with experimental results, some anomalous resonances are frequently observed that violate these selection rules. In particular, multiple quantum coherence actively involving two or three methyl protons (attached to the same carbon atom) can be transferred to observable single quantum transitions of the methyl protons, in violation of the aforementioned selection rules. Such ‘forbidden’ peaks arise due to differential relaxation rates of degenerate single quantum transitions of magnetically equivalent nuclei.^{57–59} Müller and coworkers presented a detailed analysis of the dipolar cross-correlation effects that give rise to the multi-exponential transverse relaxation of degenerate transitions. Müller has also proposed several experiments that exploit the presence of relaxation-allowed coherence transfer pathways in systems of degenerate spins.⁸

9 ADDITIONAL CROSS-CORRELATION EFFECTS

Most of the applications of cross-correlation effects in studies of biomolecules have involved the various combinations of dipole–dipole and CSA interactions and, for paramagnetic molecules, Curie spin relaxation. However, other possibilities exist as well, and a few of these are mentioned here.

Brüschweiler and Ernst²³ pointed out that cross-correlated relaxation effects can occur when a motional process simultaneously modulates a chemical shielding and a spin coupling term. For example, cross-correlated relaxation would occur for an I – S spin pair if the chemical shift of one of the spins and the isotropic scalar coupling J_{IS} were both modulated by the same motional process. Another possibility is the cross-correlation of chemical exchange effects involving multiple quantum coherences.⁶⁰ The latter effect was hypothesized to be a contributing factor in $^1\text{H}^{\text{N}}/^{15}\text{N}$ CSA/CSA cross-correlated relaxation measurements in proteins. Cross-correlation effects can be important in the analysis of dynamic frequency shifts.⁸ For example, a dynamic frequency shift (see **Dynamic Frequency Shift**, Volume 3) can result from DD/CSA cross-correlated relaxation in a two-spin-1/2 system and is manifested as an additive contribution to the apparent scalar J coupling between the two spins.⁶¹ This cross-correlation-induced J coupling is dependent on the motional properties of the spin system and thus can serve as a unique probe of molecular dynamics.

10 ELIMINATION OF CROSS-CORRELATION EFFECTS

The presence of cross-correlation effects can complicate the measurement of various relaxation rate constants by introducing additional terms into the rate equations that describe relaxation. In such cases it is desirable to devise methods for eliminating specific cross-correlation effects. These methods can be as simple as using non-selective 90° measuring pulses to eliminate multiplet effects in homonuclear spin systems,⁸ or more elaborate procedures requiring new elements to be added to the relevant pulse sequences. Among the most common type of experiments in which the elimination of cross-correlation effects is important is the measurement of heteronuclear spin relaxation rate constants. At high magnetic fields, the magnitudes of the ^1H – X dipolar and X spin CSA interactions are comparable for X representing the ^{15}N in a peptide group or the aromatic ^{13}C nuclei; consequently, cross-correlation between these two relaxation mechanisms systematically affects relaxation rate constants measured using conventional experimental methods. Boyd and coworkers⁶² demonstrated that unwanted dipole–dipole/CSA cross-correlation effects in ^{15}N longitudinal (T_1) relaxation measurements can be eliminated by broadband ^1H decoupling during the magnetization recovery period. They also proposed experimental schemes for monitoring the cross-relaxation between S_z and $2I_z S_z$ operators that results from dipole–dipole/CSA cross-correlation, and suggested that such measurements could provide information on the ^{15}N CSA tensor and on the angle θ between the principal axis of the ^{15}N CSA tensor and the ^1H – ^{15}N inter-nuclear vector. Analogous means for suppressing dipole–dipole/CSA cross-correlation effects in CPMG experiments have been proposed,^{63,64} allowing accurate measurements of spin-spin

relaxation rate constants for heteronuclei with significant chemical shift anisotropies.

11 SUMMARY

Rather than being a complicating nuisance, as it was widely perceived to be in the past, cross-correlated relaxation has turned out to be extremely valuable as the basis for many new NMR tools that have been developed for probing the structure and dynamics of biomolecules. The observed effects of cross-correlated relaxation range from subtle to dramatic. The sensitivity and resolution improvements achieved in TROSY- and CRINEPT-type experiments have made it possible to study much larger systems than was previously feasible. New experiments are available for the characterization of CSA tensors, obtaining unique structural constraints, and probing motional processes within biomolecules at an unprecedented level of detail. Although much theoretical and experimental work needs to be done to fully exploit the potential of cross-correlated relaxation phenomena, the rewards are clear and undoubtedly there are many new, valuable discoveries yet to be made in this field.

1 INTRODUCTION

Interest in selective relaxation experiments was aroused when it emerged that it was possible to interpret experimental selective relaxation parameters in terms of different relaxation contributions. Considering the dipole–dipole interaction between $I = \frac{1}{2}$ nuclei as the dominant relaxation contribution of biomolecules in solution, selective relaxation experiments can be used to calculate both selective ‘cross-relaxation’ rates σ_{ij} and individual, direct self-relaxation rates ρ_i . The observation of specific dipolar connectivities can provide useful information on several aspects of the chemical behavior of biomolecules, especially molecular structures and organization, solution dynamics, and biomolecular interactions.

2 SELECTIVE PULSE EXCITATION

Any selective relaxation experiment is performed with a specific pulse sequence which contains at least one selective excitation period. An ideal selective pulse should have the following features:^{1,2}

1. good frequency selectivity (i.e. uniform excitation of a limited spectral region);
2. short duration (to avoid effects such as relaxation, chemical shift, and coupling evolution during the pulse);
3. uniform phase behavior of the magnetization.

Several approaches, recently reviewed,^{1–3} have been developed, to generate excitation profiles to yield selective perturbation, starting from the pioneering work of Alexander.⁴ The pulse sequences proposed for selective excitation can be regarded as belonging to the following categories:

1. rectangular sequence;
2. DANTE sequence;
3. shaped sequence.

2.1 Rectangular Sequences

Rectangular sequences are single, soft pulses obtained like an ordinary hard pulse but with low-amplitude power of the radiofrequency field and a long pulse duration. Two main disadvantages are the low-frequency selectivity and the long excitation time.⁵

2.2 DANTE Sequence^{6,7}

The DANTE sequence is an ingenious system for selective excitation using high-power pulses. It consists of a sequence of 10–100 short, high-power pulses with a pulse angle $\phi < \pi/2$ and a repetition frequency $1/\tau$. The effect generated on a magnetic moment vector is similar to that of a soft rectangular pulse with a larger selectivity that improves as the number of pulses in the pulse train is increased. With respect to the soft rectangular pulse, the DANTE sequence generates a set of excitation bands at a frequency n/τ (where n is an integer 1, 2, 3, etc.) symmetrical with the transmitter frequency ω_0 .

Important improvements to the original DANTE sequence have increased the frequency selectivity (reducing the effect of side lobes of the excitation function) by pulse-shaping with DANTE⁸ and have enabled selective simultaneous excitation of two frequencies by double-DANTE sequences.⁹

2.3 Shaped Pulses

Selective relaxation experiments require the generation of sharp selective pulses that cannot be obtained from soft rectangular pulses. An almost ideal excitation profile requires smoothing of the side lobes in the frequency domain. This is now achieved by appropriate pulse-shaping procedures, which usually require a pulse-shaping spectrometer device.

Gaussian pulse shaping was one of the first shaping functions to be used.^{5,10,11} Now a number of different shaping functions are available to generate selective soft pulses for any multidimensional relaxation experiment. Tables 1 and 2 (from Kessler et al.)¹ show the main characteristics of the different soft excitation pulses and their ‘recommended’ applications.

3 THE DIPOLAR RELAXATION MECHANISM

In solution the exchange of magnetic energy between excited nuclei and the lattice occurs mainly through dipole–dipole interactions between $I = \frac{1}{2}$ nuclei. The efficiency of energy diffusion from ‘hot’ nuclei (excited) to the ‘cold’ lattice is a function of internuclear distances between spin- $\frac{1}{2}$ nuclei and the modulation of these internuclear vectors by dynamic processes, typical of molecules in solution. The time evolution of the z component magnetization of two spins I and S in a dipolar interaction has the form^{12,13}

$$\frac{d\langle I_z \rangle}{dt} = -\rho_I(\langle I_z \rangle - I_0) - \sigma_{IS}(\langle S_z \rangle - S_0) \quad (1)$$

$$\frac{d\langle S_z \rangle}{dt} = -\rho_S(\langle S_z \rangle - S_0) - \sigma_{SI}(\langle I_z \rangle - I_0) \quad (2)$$

where $\langle I_z \rangle$ and $\langle S_z \rangle$, and S_0 and I_0 are the z components and the equilibrium values of magnetization of spins I and S , ρ_I

2 SELECTIVE RELAXATION TECHNIQUES IN BIOLOGICAL NMR

Table 1 Characteristics of the Soft Excitation Forms

Form of soft excitation	Special hardware requirements ^a	Excitation function (frequency domain)		Offset-dependent phase gradient	Selectivity ^b	Side lobes	Comments
		Absorptive component	Dispersive component				
Hermite	Pulse-shaping device	Gaussian	Yes	Large, linear	Similar	No	
Rectangular DANTE ^c	None	flattened top	Yes	Large, linear	Worse	Yes	Main band and sidebands
	None	sinc	Yes	Large, linear	Worse	Yes	
90° Gaussian	Pulse-shaping device	Gaussian	Yes	Large, linear		No ^d	
Half Gaussian	Pulse-shaping device	Almost Gaussian	Yes	Large, nonlinear	Worse	No	Dispersive component shows low selectivity
Purged half Gaussian	Pulse-shaping device	Almost Gaussian	No	None	Better	No	
90° – α_{sel}	None ^e	sinc ² (near resonance)	No	None	Worse	Yes ^e	Low sensitivity to B_1 inhomogeneity
270° Gaussian	Pulse-shaping device	Almost Gaussian	Yes	Small, linear ^f	Worse	Yes	
Pulse shaping by DANTE	None	Any desired function	^g	^g	^g	^g	Main band and sidebands
Tailored excitation	None	Any desired function	^g	^g	^g	^g	

^aIn general pulse shaping by DANTE possible for all of the shaped pulses.

^bIn comparison with the Gaussian.

^bE.g. ROESY.

^cDepends on the excitation sequence.

and ρ_S the direct self-relaxation rates, and $\sigma_{IS} = \sigma_{SI}$ the ‘cross-relaxation’ rates. In this case the relaxation process assumes an exponential decay with a rate constant R_1 , the spin–lattice relaxation rate:

$$R_1^i = \rho_i + \sigma_{ij} \quad (i = I, S), (j = S, I) \quad (3)$$

For multispin interaction, as occurs in complex systems of biomolecules, the ‘nonselective’ spin–lattice relaxation rate R_1^{NS} of an i nucleus interacting with neighboring j nuclei can be described by a modified version of Equation (3):

$$R_1^{\text{NS}} = \sum_{i \neq j} \rho_{ij} + \sum_i \sigma_{ij} + R^* \quad (4)$$

with the approximation of independent pairwise interactions and considering the contribution of nondipolar relaxation processes R^* .

The explicit form of ρ_{ij} and σ_{ij} in the case of intramolecular dipolar interactions are:

$$\rho_{ij} = \frac{1}{10} \frac{\gamma_H^4 \hbar^2}{r_{ij}^6} \left(\frac{3\tau_c}{1 + \omega_H^2 \tau_c^2} + \frac{6\tau_c}{1 + 4\omega_H^2 \tau_c^2} + \tau_c \right) \quad (5)$$

$$\sigma_{ij} = \frac{1}{10} \frac{\gamma_H^4 \hbar^2}{r_{ij}^6} \left(\frac{6\tau_c}{1 + 4\omega_H^2 \tau_c^2} - \tau_c \right) \quad (6)$$

where $\hbar$ is the reduced Planck's constant, γ_H and ω_H are the proton magnetogyric ratio and Larmor frequency respectively, r_{ij} the internuclear distance, and τ_c the effective correlation time which modulates the i - j magnetic interaction.

When the excited i nucleus relaxes with j nuclei at their thermal equilibrium, the 'cross-relaxation' term vanishes¹⁴⁻¹⁶ [as the difference between the second terms of equations (1) and (2) becomes zero] and equation (4) becomes:

$$R_{li}^{SE} = \sum_{i \neq j} \rho_{ij} \quad (7)$$

where R_{li}^{SE} is the selective spin-lattice relaxation rate.

Selective excitation of two (or more) resonances adds a selective cross-relaxation term to equation (7) and the relaxation process is driven by the biselective spin-lattice relaxation rate¹⁷ R_{li}^{BS} :

$$R_{li}^{BS} = \sum_{i \neq j} \rho_{ij} + \sigma_{ij} \quad (8)$$

Proton and ^{13}C nuclei can be regarded as limiting examples of complexity for dipolar relaxation analysis and, in both cases, the possibility of using spin-lattice relaxation rates for conformational investigations is based on the ability to dissect the complex relaxation process of a multispin system.

In principle, internuclear distances can be measured for biomolecules in solution provided that (1) they have a single predominant structure or a limited number of conformers and (2) a single ρ_{ij} or σ_{ij} can be experimentally measured. This can be achieved by selective spin-lattice relaxation techniques and by combining selective relaxation rates and nuclear Overhauser effects (NOEs) as described below.

As shown by equation (4) in nonselective spin-lattice relaxation experiments on proton nuclei, the measured relaxation rate is the sum of many terms related to all the direct and σ_{ij} cross-relaxation contributions. Thus, only limited information on molecular conformation and dynamics can be obtained from nonselective proton relaxation data since several different internuclear distances and correlation times determine the experiment rate. No structural information can be obtained from the conventional ^{13}C selective relaxation of protonated carbon atoms since the one-bond C-H interaction dominates the relaxation process, and conformational analysis by studying the relaxation of quaternary carbons is complicated by the multiplicity of long-range C-H interactions.^{18,19}

The selective excitation of single (or double) protons simplifies the nuclear relaxation pathway and can be performed by a variety of techniques.^{1,2,4,20} If the experimental conditions are such that the selective relaxation process of a nucleus involved in dipole-dipole interactions is described by the above equations, simple and reliable methods of calculation of relaxation parameters from selective relaxation measurements can be used, and structural and/or dynamic information can be obtained.

Although selective relaxation parameters can be efficiently used as tools to investigate conformational properties and biomolecular interactions in small and medium-size molecules, cross-relaxation processes may be profoundly altered under the slow motion conditions ($\omega_0 \tau_c \gg 1$) typical of large biomacromolecules such as proteins, nucleic acids, and polysaccharides. When these dynamic conditions apply, the rate of transfer of spin energy between nuclei becomes much larger than the rate of transfer of energy to the lattice. The process of propagation of the magnetization in the network of dipolar-coupled spins, known as 'spin diffusion',²¹ has the effect of destroying differences in spin-lattice relaxation rates in the molecules so that all tend to the same value.²²⁻²⁴

Analyzing the relaxation process on a short timescale, i.e. using the 'initial rate approximation', it has been possible to simplify the interpretation of the results on the basis of a hypothetical two-spin system, but large problems still remain due to the extensive overlapping resonances typical of biomacromolecular spectra.

Some novel one-dimensional (1D)²⁵⁻²⁷ and two-dimensional (2D)²⁸⁻³⁰ methods have recently eliminated the 'spin diffusion' process by exclusion of selected nuclei from the dipolar-coupled bulk proton network^{29,30} or by removing the interference of all protons other than the selected pair.²⁵⁻²⁷ In the era of 1D, 2D, three-dimensional, and multidimensional NMR these methods can open up a new age for the application of selective relaxation measurement to study large biomacromolecules.

4 GENERAL REMARKS ON SELECTIVE RELAXATION EXPERIMENTS

In order to perform selective relaxation experiments, the use of pulse sequences able to perturb the nuclear spin population is required. Initial relaxation rates can be obtained provided that the experiment is correctly carried out and that theoretical problems do not quench the dipolar relaxation strategy. As the recovery of the longitudinal component of nuclear magnetization very rarely follows a true exponential decay, it is important to analyze under what circumstances these undesired effects can be avoided. Unfortunately the main effects that alter the exponential behavior of the magnetization are intrinsic, as they arise in coupled spin systems and are due to dipole-dipole 'cross-relaxation' effects and scalar coupling.^{31,32}

4.1 Cross-Relaxation Effects

As shown by equations (1) and (2), the recovery of the longitudinal component of the magnetization is usually described by two constant rates ρ and σ , and only under special conditions is this behavior a pure exponential. This is the case

for ^{13}C magnetization measured under conditions of continuous broadband proton decoupling, where proton irradiation sets up and maintains a constant spin population of allowed energy levels such that cross relaxation no longer affects the recovery curve. Similar behavior is expected for selective proton relaxation in cases of weak dipolar coupling or when the effect of cross-relaxation diffusion is truncated using the initial slope approximation. In the latter case the experimental relaxation parameter is calculated by measuring the initial rates in the semi-logarithmic plot of reduced intensity $(I_0 - I_z)/2I_0$ vs. delay times. In more general cases, especially in biological systems, the presence of a network of dipolar-coupled spins induces cross-relaxation contributions that change the pure exponential decay. Nevertheless, at least for small and medium-size biomolecules and for dipolar interactions within a 3.5 distance, the initial rate approximation can be used to interpret the data in terms of two-spin systems and to calculate by numerical simulation the direct self-relaxation rate and the 'cross-relaxation' contributions. A more complex situation occurs when the fast motion conditions $\omega_0^2\tau_c^2 \ll 1$ do not hold, as in large biomolecules. Under these conditions, due to spin diffusion, the initial slope approximation is no longer valid, especially for long-range interactions, and only recently has it been possible to determine by virtue of synchronous nutation experiments^{25–27} the structural properties of proteins from cross-relaxation data obtained by selective relaxation measurements.

4.2 Scalar Coupling

In strongly coupled spin systems, the transition probabilities for the components of a spin multiplet are no longer equal. An important element of symmetry is thus lost, even though the excitation pulse acts equally on all multiplet components. Even for a single two-spin system AB, the zero quantum, single quantum and the double quantum transition probabilities do not assume the classical form,^{31–33} but a mixing term W_{AB} appears. It is this last term W_{AB} that causes different recovery curves for the components of a spin multiplet with a specific deviation from pure exponential magnetization decay.

However the perturbative effect of scalar coupling on the behavior of the magnetization recovery curve can be considered a priori. Moreover the 'classical' relaxation equations are still valid when $\Delta\omega/J > 10$, where $\Delta\omega$ is the difference in chemical shift between two spins and J is their scalar coupling constant. This is a general condition met in studying biological systems. Again the synchronous nutation experiment²⁷ has simplified the problem of correctly calculating the relaxation parameter in the presence of strong scalar coupling, by removing all scalar interactions between spins that are irradiated (active) and at Boltzmann equilibrium (passive). Although the effect of strong scalar coupling between irradiated (active) spins can still affect the recovery curve, its contribution can be taken into account by simple numerical analysis.

5 APPLICATION OF SELECTIVE RELAXATION TECHNIQUES IN BIOLOGICAL SYSTEMS

Many papers have fairly recently been published^{25,34–38} proposing the use of selective relaxation experiments to investigate biological systems. For simplicity, proton homonuclear

and heteronuclear interactions and their field of application will be treated separately.

5.1 Homonuclear Selective Relaxation Experiments

In ^1H homonuclear spin systems, the nonselective inversion recovery, $180^\circ\text{-}\tau\text{-}90^\circ$ pulse sequence gives partially relaxed spectra in which it is possible to follow the recovery of the Boltzmann equilibrium for each resonance by individual constant rates (R_1^{NS}) which are the sum of two contributions: the direct and the cross-relaxation terms [as described by equation (4)]. It has been shown by Freeman et al.¹⁴ that cross relaxation may be negligible provided that the 180° pulse selectively excites single-proton resonances. In particular, if the initial relaxation is monitored after selective population inversion of proton i , i.e., short delays are used between the selective and the nonselective observing 90° pulse, the initial recovery rate of the magnetization (R_{1i}^{SE}) is described by equation (7). At longer delay times, cross relaxation becomes significant, as can be observed from the intensity changes of the resonances of protons dipolarly coupled to the excited proton. It follows that selective excitation techniques can be used to achieve a simplification of the proton relaxation process and to calculate the selective dipolar relaxation contribution to the observed spin–lattice relaxation rate.

The initial selective relaxation rate R_{1i}^{SE} is an important parameter which can be used to obtain information on: (1) relaxation mechanisms, (2) molecular dynamics, and (3) molecular conformations.

1. In molecular systems which satisfy the extreme narrowing condition $(\omega_0\tau_c)^2 \ll 1$, for proton i , the ratio between the nonselective relaxation, R_1^{NS} , and R_{1i}^{SE} is diagnostic of the efficiency of the dipole–dipole relaxation mechanism, since this ratio, F_i , is equal to 1.5 for a relaxation pathway completely dominated by the i – j proton dipolar interactions.³⁹
2. As shown in Figure 1, F_i also depends on $\omega_0\tau_c$ and, hence, for rigid isotropically reorienting molecules, motions can be quantified from the latter parameter.³⁹
3. The combined use of R_{1i}^{SE} and homonuclear Overhauser effects, NOEs, yields an absolute evaluation of σ_{ij} rates since, neglecting cross-polarization effects, the following relationship holds⁴⁰

$$\text{NOE} = \sigma_{ij}/R_i(\text{SE}) \quad (9)$$

where NOE is the Overhauser effect on proton i upon selective excitation of proton j .

The calculation of the cross-relaxation rate relative to a single i – j dipolar interaction is also possible by the simultaneous double excitation of protons i and j . If selectivity in the double excitation can technically be achieved, the relaxation process is driven by the biselective relaxation rate, R_{1i}^{BS} , as shown by equation (8).

It should be noted that the initial conditions for the evaluation of R_{1i}^{BS} are critically important because the peak intensities observed in the partially relaxed spectra are determined by the relaxation process and the time-dependent i – j NOE.^{31,41}

Homonuclear selective relaxation experiments are widely used to investigate different properties of biological systems. The most interesting approaches are related to the analysis of:

Figure 1 (a) Dependence of $F = R_i(\text{NS})/R_i(i)$ versus $\log \omega_0 \tau_c$. (b) Behavior of $RSE/1$ (1), $RNS/1$ (2), and σ_{ij} (3) for a two-spin system under different dynamic conditions; (1), (2), and (3) are readily generalized for proton i , involved in multiple interactions with several protons, $i \neq j$. (Reproduced by permission of Academic Press from N. Niccolai et al.³⁹)

1. conformational and dynamic properties of biomolecules in solution;
2. the interaction process between ligand and biological receptors;
3. the behavior of water in the presence of large, organized biological systems.

5.1.1 Conformational and Dynamic Properties of Biomolecules in Solution

The network of intramolecular dipolar connectivities in small to medium-size biomolecules can be easily evaluated by selective relaxation experiments. The most suitable approach consists first of calculating the cross-relaxation rates between selective proton pairs as the difference between selective and bisselective relaxation experiments:

$$\sigma_{ij} = R_{1i}^{\text{BS}} - R_{1i}^{\text{SE}} \quad (10)$$

$$\sigma_{ji} = R_{1j}^{\text{BS}} - R_{1j}^{\text{SE}} \quad (11)$$

in which $\sigma_{ij} = \sigma_{ji}$ are the cross-relaxation values obtained from analysis of the relaxation properties of the i and j

nuclei, respectively. Selective homonuclear NOE experiments can also be used to evaluate σ_{ij} . Figure 2 shows an example of proton-selective and bisselective experiments used for calculating σ_{ij} . The effect of the additional cross-relaxation contribution to the magnetization recovery process in the bisselective experiment, is evident.

As shown by equation (6) and Figure 3, σ_{ij} contains both structural (r_{ij}) and dynamic (τ_c) information.⁴² Constant calibration distances are required for the calculation of the effective correlation time τ_c . This is easily achieved by considering independent conformational distances as geminal interactions of CH_2 groups, *ortho* protons of aromatic residues, etc.

As shown in Figure 1, $F_1 = R_{1i}^{\text{NS}}/R_{1i}^{\text{SE}}$ can be used as a probe for molecular motion assuming as dominant the intramolecular dipolar mechanism. Carbon-13 relaxation measurements (see next section) obtained under broadband proton decoupling can also be used to map the distribution of motions along a biomolecule or to verify isotropic tumbling in systems with restricted internal flexibility. A detailed description of the modulation of the dipole-dipole interaction allows selected interproton distances, from which the solution conformation can be derived, to be calculated with confidence. From the first papers^{39,43,44} in which this approach was proposed, nearly every class of biological molecule was investigated: amino acids,^{43,45} peptides,⁴² carbohydrates,⁴⁶ oligosaccharides,^{47,48} drugs,^{49,50} natural products,^{37,51,52} etc.

Recently when the 2D approach for studying dipolar networks seemed to diminish the importance of these selective relaxation studies, a new selective experiment was proposed which enabled large macromolecules such as proteins to be investigated²⁵ (Figure 4). According to this new approach, one or two proton resonances are simultaneously excited by an amplitude modulated radiofrequency field which forces the magnetization vectors to undergo simultaneous motion defined as ‘synchronous nutation’.^{25–27} Time-dependent analysis under different initial conditions allows calculation of the direct self-relaxation rate or the ‘cross-relaxation’ term. In the ‘synchronous nutation’ experiment, the neighboring spins do not affect the magnetization behavior of the selectively isolated spin system even in the presence of the spin diffusion typical of slow molecular tumbling $\omega_0 \tau_c \gg 1$ conditions. Conformational studies (through selected-pair distance determination) by selective relaxation measurements in large biomacromolecules appear to be a valid alternative to the classical approach based on 2D analysis of dipolar-coupled spin systems.

5.1.2 Intermolecular Interaction: Ligand–Macromolecular Receptor

Ligand–macromolecule interactions can be detected by selective relaxation measurements. The formation of intermolecular adducts affects nonselective and selective spin–lattice relaxation rates to different extents, assuming that fast chemical exchange occurs between the bound and free environments with respect to both the chemical shift difference and the proton relaxation rate.⁵³

If only two environments are considered, the relaxation parameters are expressed by:

$$R_{\text{obs}}^A = \chi_f R_{1f}^A + \chi_b R_{1b}^A \quad (12)$$

Figure 2 Proton-selective and biselective partially relaxed spectra obtained by selective inversion of the magnetization of H-1' (a) and of both H-1'–H-3 (b) protons of a 0.15 mol dm⁻³ gentiobiose octaacetate solution in dimethyl sulfoxide-*d*₆. *T* = 300 K. The delay values between the selective and nonselective pulses were: 5, 10, 20, 40, 80, 100, 200, 400, 600, 800, 1000, 2000, and 10 000 ms

Figure 3 Isosigma contours for $\log \omega_0 \tau_c$ vs. interproton distances calculated from equation 6; the selected σ values are expressed in s⁻¹. (Reproduced by permission of Elsevier from N. Niccolai, L. Pogliani, C. Rossi, P. Corti, and W. A. Gibbons, *Biophys. Chem.*, 1984, **20**, 217)

where χ_f and χ_b are the ligand fractions in the free and bound environments. Since $\chi_f + \chi_b = 1$ and taking $\chi_b \ll 1$, equation (12) becomes:

$$R_{\text{obs}}^A = R_{\text{lf}}^A + \chi_b R_{\text{lb}}^A \quad (13)$$

Figure 4 Selective inversion–recovery measurements of the aromatic protons H^δ and H^ε of the tyrosine (Tyr) residue in bovine pancreatic trypsin inhibitor dissolved in ²H₂O at 327 K. The inset shows the aromatic region (between 8.2 and 5.8 ppm) of the 1D spectrum (eight scans); the arrows indicate the shifts of H^ε at 6.30 ppm and of H^δ at 7.20 ppm. Lower part: normal inversion–recovery measurement of H^ε in Tyr²³ using selective pulses and direct observation of H^ε. Upper part: inversion–recovery of H^δ using selective pulses and Hartmann–Hahn transfer from H^δ to H^ε. (Reproduced by permission of the American Chemical Society from B. Boulat, R. Konrat, I. Burghardt, and G. Bodenhausen, *J. Am. Chem. Soc.*, 1992, **114**, 5412)

where A = SE or NS. From equation (13) it emerges that only experimental parameters broadly affected by the ligand–macromolecular interaction make the second term of equation (13) significant. Binding of a ligand to a macromolecular receptor slows down its reorientation motion from $\omega_0 \tau_c \ll 1$ to $\omega_0 \tau_c \gg 1$. In diamagnetic systems where the dipole–dipole interaction is the dominant relaxation mechanism, entering into the slow-motion region does not significantly alter the nonselective spin–lattice relaxation rates [equation (4)]. On the contrary, the selective relaxation of the bound ligand can be expected to be quite different from that

Figure 5 $R_{1S}/1$ and $R_{1SE}/1$ of a proton pair versus $\omega_0\tau_c$ assuming a constant r_{i-j} distance (1.77 Å) for the $i-j$ dipolar interaction. The equilibrium between the ligand molecules in the bulk ($\omega_0\tau_c \ll 1$) and DNA-bonded ($\omega_0\tau_c \gg 1$) is also shown. (Reproduced by permission of Elsevier from C. Rossi, A. Donati, and M. R. Sansoni, *Chem. Phys. Lett.*, 1992, **189**, 278)

of the free ligand in solution as shown in Figure 5 for a ligand–DNA interaction.³⁶

Since the study of biomolecular interactions by selective relaxation measurement is based on a slowing of ligand molecular motion, the effect of the macromolecular receptor on the viscosity of the system must be considered. Temperature-dependent analysis of R_{1S}^{NS} can address this point. In fact as seen in Figure 5, fast-motion ($\omega_0\tau_c \ll 1$) and slow-motion ($\omega_0\tau_c \gg 1$) conditions show opposite slopes, so hypothetical, drastic changes in viscosity due to the receptor site can be monitored simply by following R_{1S}^{NS} dependence on temperature.^{36,54} This method is very powerful since it has a wide range of applications in biological systems. As the information is gained from selective relaxation rates of the ligand, ill-defined receptors in biological samples⁵⁵ such as blood whole cells etc. can be investigated and receptor purification followed.

A wide range of ligand–biomacromolecule interactions have been investigated by selective spin–lattice relaxation rate analysis;⁵⁶ these include enzyme–substrate,⁵³ drug–membrane interactions,⁵⁷ and recently ligand–DNA,³⁶ for the purpose of identifying potential mutagens and toxic compounds. This approach can also be used to calculate the association constant for the interaction processes.⁵⁸

5.1.3 Water Selective Relaxation in Large Organized Biological Systems

Water proton relaxation rates have been found to correlate with the physiological and pathological state of the cell as well as to the conformational state of cell constituents.^{59–61} Experimental evidence that water selective relaxation is faster than nonselective water relaxation rates in protein solutions and cell suspensions has focused attention on the relaxation mechanism of water protons in large organized

systems.^{38,62–65} The water spin–lattice relaxation (R_{1W}) may be described as the sum of two contributions:⁶⁶

$$R_{1W} = R_{1A} + R_{1B} \quad (14)$$

where R_{1A} and R_{1B} are the intra- and inter-molecular relaxation rates. The intramolecular term is due to:

$$R_{1B} = R_{1WW} + R_{1WM} \quad (15)$$

R_{1WW} is the dipolar contribution due to intramolecular water–water interactions and R_{1WM} that arising from water–macromolecule (or cell constituent) interactions.³¹ The latter interaction can yield direct ρ_{WM} and cross-relaxation σ_{WM} contributions from simultaneous water and macromolecule proton excitation:

$$R_{1WM} = \sum \rho_{WM} + \sum \sigma_{WM} \quad (16)$$

If the water relaxation rate is measured in the selective mode, only a small fraction of the macromolecule protons are excited and the σ_{WM} term disappears. It follows that in the presence of large biological surfaces:⁶⁵

$$R_{1W}^{NS} - R_{1W}^{SE} = \sum \sigma_{WM} \quad (17)$$

where R_{1A} and R_{1WW} are constants in nonselective and selective experiments respectively. Experimental evidence obtained for protein solutions and cell culture suspensions shows that the difference between nonselective and selective relaxation rates [equation (17)] are not only due to the dynamic change in the solvent molecules but also to dipolar intermolecular connectivities between the solvent and the surface of hydrophilic regions of macromolecules. This suggests that it would be useful to use the complete set of relaxation parameters, such as R_{1W}^{NS} , R_{1W}^{SE} , and σ_{WM} to investigate the physiological and pathological state of cells or to study drug–cell and virus–cell interactions;⁶⁷ R_{1W}^{NS} to probe essentially dynamic features of the heterogeneous systems, and R_{1W}^{SE} and σ_{WM} to study the water–macromolecule magnetic energy transfer process, which is intimately linked to the solvent exposed interface structure assumed by the biological material.

5.2 Heteronuclear Selective Relaxation Experiments

Our discussion will be limited to the ^{13}C nucleus, due to its importance for verifying dynamic and structural information on biological systems.

In spite of the low sensitivity of heteronuclei with respect to protons, several advantages exist. Carbon-13 signals are spread over a large chemical shift range (over 300 ppm). The carbon resonances can be treated as single resonances removing proton scalar coupling by a broadband decoupling pulse. Under these conditions the carbon relaxations can be regarded as pure exponential, determined by a single contribution: the direct self-relaxation term. Furthermore, relaxation contributions due to intermolecular interactions are seldom significant (as the carbons are shielded by the proton surface) and, in natural abundance experiments, homonuclear ^{13}C – ^{13}C dipolar interactions are rare due to ^{13}C isotopic dilution. These properties make carbon relaxation a suitable parameter for investigating solution properties of biomolecules.

5.2.1 ^{13}C Selective Relaxation

In conventional ^{13}C relaxation experiments (obtained by broadband proton decoupling), cross relaxation between carbon nuclei is ignored and the measurement gives the selective, direct carbon spin–lattice relaxation rate:

$$R_{1C}^{\text{SE}} = \sum \frac{1}{10} \frac{\hbar^2 \gamma_H^2 \gamma_C^2}{r_i^6} \left[\frac{3\tau_c}{1 + \omega_C^2 \tau_c^2} + \frac{6\tau_c}{1 + (\omega_H + \omega_C)^2 \tau_c^2} + \frac{\tau_c}{1 + (\omega_H - \omega_C)^2 \tau_c^2} \right] \quad (18)$$

R_{1C}^{SE} of protonated carbons are dominated by the dipolar interaction between bonded proton–carbon nuclei.^{17,18} In this case the internuclear proton–carbon distance can be assumed to be constant and the effective correlation time calculated. In flexible molecules, a mapping of dynamic properties may be obtained from the R_{1C}^{SE} of different carbons. If continuous broadband proton decoupling is replaced by a selective 180° proton pulse, applied to the i nucleus, with the first 180° carbon pulse the initial rate of the longitudinal magnetization of carbon is:^{68–70}

$$R_{1C}^{\text{BS}} = R_{1C}^{\text{SE}} + \xi \sigma_{\text{CH}_i} \quad (19)$$

where R_{1C}^{BS} is the biselective carbon relaxation rate $\xi = \gamma_H/\gamma_C$ and σ_{CH} the single proton–carbon ‘cross-relaxation’ term. When the selective 180° proton pulse is replaced by a proton perturbation which can invert the spin equilibrium of the entire proton population, the carbon relaxation is described by:^{69–71}

$$R_{1C}^{\text{NS}} = R_{1C}^{\text{SE}} + \xi \sum \sigma_{\text{CH}_i} \quad (20)$$

The following dynamic and structural information is obtained by comparing R_{1C}^{SE} , R_{1C}^{BS} , and R_{1C}^{NS} measurements.

5.2.1.1 Dynamic analysis. The $R_{1C}^{\text{NS}}/R_{1C}^{\text{SE}}$ ratio takes a value in the range 2.99–1, depending on the molecular motion. In this way the value of the $R_{1C}^{\text{NS}}/R_{1C}^{\text{SE}}$ ratio allows the correlation times for each molecular moiety to be determined (or at least the limit value of τ_c). The $R_{1C}^{\text{NS}}/R_{1C}^{\text{SE}}$ ratio in particular is a very useful parameter for evaluating the effective correlation time of nonprotonated carbon atoms.

5.2.1.2 Structural analysis. The difference between R_{1C}^{BS} and R_{1C}^{SE} gives the cross relaxation term $\sigma_{\text{C}_i\text{H}_A}$ for each ^1H – ^{13}C magnetic interaction which contains distance information. This method has been demonstrated with different natural products, giving reliable results.^{69–71}

5.2.2 Selective Proton–Carbon NOEs

Several authors have shown that selective proton–carbon NOEs, (^1H) ^{13}C -NOE, can be generated.^{72–74} When a selective pulse is used to saturate a single proton then ‘cross relaxation’ between the irradiated proton and the carbon microenvironment occurs. The (^1H) ^{13}C -NOE is described by:^{75,76}

$$(^1\text{H}_A)^{13}\text{C}_i - \text{NOE} = \frac{\sigma_{\text{C}_i\text{H}_A}}{R_{1C}^{\text{SE}} + R_{1C}^*} \quad (21)$$

Figure 6 Carbon-13 spectra of 0.5 mol dm^{−3} rifamycin in CDCl₃ recorded on a Varian XL-200 spectrometer at 296 K: (a) ^{13}C spectrum after irradiation of the phenolic hydroxyl proton; (b) as (a) but with the decoupler set ‘off-resonance’. (c) Difference spectrum (b)–(a). The presaturation selective pulse on the phenolic hydroxyl proton had a 10 s duration and 0.5 W power. During the acquisition of the FIDs the decoupler was on with a power of 4 W in the broadband mode. The structure of rifamycin S is shown. (Reproduced by permission of the American Chemical Society from N. Niccolai et al.⁷⁵)

where $\sigma_{\text{C}_i\text{H}_A}$ is the selective ‘cross relaxation’, R_{1C}^{SE} the selective carbon relaxation rate, and R_{1C}^* the relaxation contribution due to nondipolar interactions [in paramagnetic systems this term often quenches the (^1H) ^{13}C -NOE]. Thus by combining selective NOEs with carbon relaxation rates, specific distance calculations can be obtained.

Although care must be taken in dealing with large macromolecules when magnetization diffusion occurs between spins, this method has been usefully applied to investigate the conformation of biological molecules such as antibiotics, peptides, natural components,^{77–79} etc. Figure 6 illustrates the capacity of (^1H) ^{13}C - NOE to discriminate the carbon microenvironment by selective proton perturbation.⁷⁵

1 INTRODUCTION

Many of the biologically relevant dynamic processes that take place in naturally occurring materials may be considered to be slow on the NMR timescale. This implies that the characteristic frequencies of the motions are comparable to or lower than the width of the NMR spectra that would be obtained in the absence of any molecular motion. Since virtually all nuclei commonly employed for NMR studies of biological systems yield rigid lattice spectra less than 1 MHz wide, a slow process may be defined for present purposes as one whose correlation times τ_C are longer than $(2\pi \times 10^6)^{-1}$ s. This article describes how NMR can be used to investigate such motions, with particular reference to biological studies.

There exists a wide range of NMR techniques available for probing low-frequency molecular dynamics. The methods themselves are by no means applicable only to biological systems, and indeed many of them were originally developed primarily to study synthetic materials. Most of the techniques are discussed in detail in other entries of this Encyclopedia. As far as NMR-observable nuclei are concerned, ^1H , ^{13}C , ^{14}N , and ^{31}P , which are, of course, abundant in biologically relevant compounds, can all be used in principle to investigate slow motions. In addition, the use of ^2H -labeled materials has now become almost commonplace, and has permitted highly detailed site-specific dynamic NMR studies even in extremely complex systems.

Spin–lattice relaxation rates $1/T_1$ are essentially measures of the amplitudes of motional processes occurring at the Larmor frequency ω_0 of the probe nucleus. Thus, measurement of T_1 as a function of ω_0 provides a means of determining the motional frequency spectrum. For purposes of resolution and sensitivity, commercial spectrometers employ high magnetic fields. In the case of protons, for example, $\omega_0/2\pi$ ranges between 60 and 750 MHz, so that measurement of ^1H T_1 on a complete range of standard spectrometers could yield dynamic information over about one order of magnitude on the frequency scale. Field cycling techniques^{1,2} enable the determination of T_1 at frequencies lower than the standard high Larmor frequencies and greatly extend the range of

the motional frequency spectrum that can be observed. This has particular significance for the study of slow motions in complex systems, where several processes may contribute to the overall spin relaxation mechanism. The application of field cycling for measuring ^1H T_1 dispersions has been instrumental in characterizing collective motions in proteins³ and in phospholipid membranes.⁴

Whereas spin–lattice relaxation is essentially nonadiabatic and reflects exclusively those motions with frequency components at ω_0 , transverse spin relaxation is affected in addition by adiabatic dephasing mechanisms due to processes with smaller rate constants, on the order of the rigid lattice linewidth. Transverse relaxation times are most commonly measured using spin echo experiments in which inhomogeneous (i.e., static) contributions to the magnetization dephasing process are refocused. The simplest spin echo experiment consists of a 90° pulse followed by a delay τ , after which a refocusing pulse (180° or 90°) is applied. An echo is formed a period τ after the second pulse, the intensity of which decreases with increasing τ .^{5,6} If the dominant motional process is fast in the sense that the correlation time τ_C is shorter than τ then the echoes decay exponentially, and it is possible to extract a single transverse relaxation time T_{2E} . For slower motions, however, for which τ_C is comparable to or longer than τ , the effective relaxation rate itself depends on the value of τ ,⁷ and the echo decay can no longer be described by a single exponential. In fact, the precise form of the echo decay function depends sensitively on the nature of the underlying motional process.

Although this phenomenon has been understood since the early days of pulsed NMR spectroscopy,⁷ its potential applications in the study of slow processes in complex phases such as biological membranes have been recognized only relatively recently.⁸ In practice, rather than measure the form of the simple spin echo decay function, multipulse trains such as the Carr–Purcell–Meiboom–Gill (CPMG) sequence^{9,10} and its quadrupolar analog¹¹ are employed. In these experiments, instead of a single refocusing pulse, a series of equally spaced refocusing pulses is applied, resulting in the formation of an echo train. For samples containing a single spin label, the echoes decay monoexponentially with a time constant T_{2E}^{CP} , which depends on the pulse spacing τ . The form of the pulse spacing variation of T_{2E}^{CP} is indicative of the distribution of correlation times for the responsible motional processes, whilst the absolute values of T_{2E}^{CP} reflect their effective amplitudes.¹²

Transverse spin relaxation techniques, employing either ^2H or ^{31}P as the probe nuclei, have been applied to study a variety of mechanisms such as collective motions^{12–15} and lateral diffusion⁸ in biological membranes. An alternative but related approach for observing slow motions involves rotating frame relaxation measurements.¹⁶ The locking-field dependence of $T_{1\rho}$ is analogous to the pulse spacing dependence of T_{2E}^{CP} ,¹⁷ and has been exploited to characterize low-frequency dynamics in phospholipid membranes.^{18,19}

Ultraslow exchange NMR methods directly measure the time variation of the resonance frequency as a result of molecular reorientation.²⁰ The basic requirement for all experiments of this type can be expressed by the relation $T_1 > \tau_C > T_{2E}$. This approach affords the possibility to study processes with effective correlation times of up to several seconds, depending on T_1 of the resonant nucleus. In the two-dimensional version of the experiment,²¹ cross peaks

appear connecting the different frequencies experienced by the spins. In general, the resonance frequency of a particular spin is determined by the orientation Ω of the dominant spin interaction tensor relative to the static magnetic field. Consequently, it is rather straightforward to interpret the exchange spectra in terms of the time variation of Ω .

The choice of experiment to use for investigating a particular system will be dictated by the expected timescale of the motional process of interest and, of course, by the materials available. In the case of ultraslow motions, one of the exchange type of experiments would be most suitable, although the condition $\tau_C > T_{2E}$ is rarely fulfilled in biological systems. For complex collective and/or low-amplitude processes, one of the spin relaxation techniques (T_1 , T_{2E}^{CP} , or $T_{1\rho}$) would be most appropriate. The field cycling 1H T_1 approach undoubtedly offers the greatest dynamic range—typically six orders of magnitude in frequency. This is especially useful when dealing with collective motions with broad distributions of correlation times. The method is limited at low frequencies, however, by internal field effects, which render ambiguous the interpretation of any cutoffs that may appear in the T_1 dispersion profiles. The same restrictions apply to $T_{1\rho}$ measurements but not to T_{2E}^{CP} studies. This, together with the simplicity of the experimental techniques, makes pulse-frequency-dependent T_{2E}^{CP} experiments particularly attractive for characterizing slow motions in biological systems. In the following sections, frequency-dependent transverse relaxation is described in more detail, with particular reference to its application in the study of slow motions in biological membranes.

2 OBSERVATION OF SLOW MOTIONS: PULSE-FREQUENCY-DEPENDENT SPIN RELAXATION

Nuclear spin relaxation times provide information regarding the timescale, symmetry and amplitude of molecular motion. In order to distinguish between different possible mechanisms, it is advisable if not essential to exploit each of these three aspects of the dynamics. A simple and effective method for achieving this in the slow motional regime involves determining the pulse spacing and orientation dependence of transverse spin relaxation times T_{2E}^{CP} .

2.1 Spin Echo Pulse Trains

The CPMG pulse sequence^{9,10} and its quadrupolar equivalent¹¹ measures the decay of successive spin echoes as illustrated schematically in Figure 1 (top). If the motional correlation time τ_C is of the same order of magnitude as the pulse spacing τ then the echo decay rate $R_{2E}^{CP} = 1/T_{2E}^{CP}$ depends on τ . Generally, the form of the pulse spacing dependence is characteristic of the motion responsible for the relaxation. This is illustrated in Figure 1 (bottom), which shows R_{2E}^{CP} pulse frequency dispersions [$R_{2E}^{CP}(\omega)$, $\omega = 1/\tau$] for three different types of motion. The Markov process with a single correlation time τ_C exhibits a Lorentzian dispersion with a plateau at low frequencies ($\omega \ll 1/\tau_C$) and an inverse square dependence $R_{2E}^{CP} \propto \omega^{-2}$ at higher frequencies.²² More

Figure 1 Top: Schematic of CPMG pulse sequence, showing echo decay. Bottom: Dependence of transverse relaxation rate R_{2E}^{CP} on pulse frequency $\omega = 1/\tau$ for (a) a single Markov process, and (b) three-dimensional and (c) two-dimensional collective orientational fluctuations

complex processes exhibit, in addition, an intermediate dispersion regime characteristic of the motion. Thus, collective orientational fluctuations provide a $R_{2E}^{CP} \propto \omega^{-1/2}$ dispersion in ‘three-dimensional’ phases (e.g., nematic liquid crystals),²³ whilst in ‘two-dimensional’ phases (e.g., bilayer membranes), the relaxation rate is inversely proportional to the pulse frequency: $R_{2E}^{CP} \propto \omega^{-1}$.^{12,15} The experimentally accessible frequency range of R_{2E}^{CP} depends, in general, on the sensitivity of the observed spin and on the form of the relaxation dispersion. For ^{31}P , in biological membranes, for example, it is possible to measure R_{2E}^{CP} at frequencies between 10^2 and 10^5 s⁻¹, which is sufficient to cover the relevant slow motional regime.¹⁵

There are two possible approaches to the analysis of transverse spin relaxation measurements, and some consideration should be given as to which method is most appropriate for each individual case. Motional narrowing limit expressions, which are usually adequate for the interpretation of spin–lattice relaxation experiments, cannot always be applied to transverse relaxation. In particular, for systems undergoing slow motions, it will generally be necessary to solve numerically the equations of motion for the relaxing spins.

2.2 Full Numerical Analysis

The starting point for a full numerical analysis of spin relaxation is the stochastic Liouville equation^{24,25}

$$\frac{\partial}{\partial t} \hat{\rho}(\Omega, t) = -\frac{i}{\hbar} \hat{\mathcal{H}}^x(\Omega) \hat{\rho}(\Omega, t) - \hat{\Gamma}(\Omega) [\hat{\rho}(\Omega, t) - \hat{\rho}_{eq}(\Omega)] \quad (1)$$

which describes the time dependence of the spin density matrix $\hat{\rho}(\Omega, t)$ under the influence of the spin Hamiltonian $\hat{\mathcal{H}}^x(\Omega)$ and the stochastic operator $\hat{\Gamma}(\Omega)$, for the various motional processes. The Euler angles Ω define the orientation of the dominant spin interaction tensor relative to a set of laboratory axes. Fortunately, for the purposes of interpreting transverse relaxation rates due to slow motions, it is often possible to separate the coupled differential equations [see equation (1)] into independent subsets describing the time variation of specific density matrix elements. Thus, the relevant part of equation (1) can be represented by a reduced set of differential equations, written in matrix form as^{26–28}

$$\frac{\partial}{\partial t}[\rho_{ij}(\Omega, t)] = -[i\mathbf{W}(\Omega) + \mathbf{K}(\Omega)][\rho_{ij}(\Omega, t)] \quad (2)$$

where $\rho_{ij}(\Omega, t)$ are the single quantum coherence components of $\hat{\rho}(\Omega, t)$, with $j = i \pm 1$. $\mathbf{K}(\Omega)$ is a rate matrix with elements determined by the discretized stochastic operator $\hat{\Gamma}(\Omega)$.^{26,27} Thus, $K(\Omega_{mn})$ is the rate constant for population transfer from site n to site m and $K(\Omega_{mm}) = -\sum_{n \neq m} K(\Omega_{mn})$. The diagonal matrix $\mathbf{W}(\Omega)$ contains the free precession frequencies for each site, m . In order to solve equation (2) it is convenient first to symmetrize $i\mathbf{W}(\Omega) + \mathbf{K}(\Omega)$ by a similarity transformation and then apply an efficient eigenvalue method.^{29,30}

Spin echo experiments can be simulated by successive application of equation (2) to describe each stage of the pulse sequence.^{31,32} Refocusing pulses can be treated as ideal rotations, inducing an instantaneous 180° phase shift in $\rho_{ij}(\Omega, t)$. The transverse relaxation rate R_{2E}^{CP} for a given pulse spacing τ is then³³

$$R_{2E}^{CP} = -\ln[M(2\tau)/M(0)]/2\tau \quad (3a)$$

$$M(t) = \sum_m \sum_i \rho_{i i-1}(\Omega_m, t) \quad (3b)$$

Note that for a homogeneous system, it is not necessary to evaluate the entire CPMG sequence, but it suffices to calculate just the first echo and apply equations (3a) and (3b).³⁴

2.3 Motional Narrowing Limit Expressions

For slow low-amplitude processes, it is conceivable that motional narrowing limit theory³⁵ may be applied to account for transverse spin relaxation. Exact analytical expressions for R_{2E}^{CP} valid in this regime have been derived.^{7,17,22} A useful approximate version of these derivations is^{23,33}

$$R_{2E}^{CP} \approx \frac{3}{2} C J_0^{\text{lab}}(\omega) \quad (4)$$

where $J_0^{\text{lab}}(\omega)$ is the spectral density of the motion at the pulse frequency $\omega = 1/\tau$ and C is the effective interaction strength parameter (e.g., $C = \frac{2}{3} \langle \Delta \sigma^2 \rangle$ for ^{31}P and $C = \frac{3}{8} \langle (e^2 q Q / \hbar)^2 \rangle$ for ^2H). For certain dynamic models, analytical expressions are available or can be derived for $J_0^{\text{lab}}(\omega)$. Otherwise, they may be evaluated numerically using the same finite grid point approach^{26,27} described above. In this case, we have^{36,37}

$$J_M^{\text{lab}}(\omega) = (F_{20}^{\text{mag}})^{-2} \left[\sum_{m,n} F_{2M}^{\text{lab}}(\Omega_m) F_{2M}^{\text{lab}*}(\Omega_n) X_m^{(0)} X_n^{(0)} \times \sum_k X_m^{(k)} X_n^{(k)} j^{(k)}(\omega) \right] \quad (5a)$$

$$j^{(k)}(\omega) = \frac{8}{\pi^2} \frac{\lambda^{(k)}}{(\lambda^{(k)})^2 + (\frac{1}{2}\pi\omega)^2} \quad (5b)$$

where $\lambda^{(k)}$ and $X^{(k)}$ are the eigenvalues and corresponding eigenvectors of the stochastic operator $\mathbf{\Gamma}$, obtained by diagonalizing the symmetrized rate matrix $\mathbf{K}^s$. The $F_{2M}^{\text{lab}}(\Omega_m)$ are the components of the magnetic interaction tensor for the m th site, expressed in the laboratory axis system (z parallel to $\mathbf{B}_0$). Similarly, F_{20}^{mag} is the zeroth component of the interaction tensor expressed in its principal axis system. Note that the Lorentzian reduced spectral density $j^{(k)}(\omega)$ defined above uses the inverse pulse spacing as the frequency variable, and for this reason differs from standard expressions for spectral densities in magnetic resonance, which generally involve the Larmor frequency ω_0 .

Combining equations (4), (5a), and (5b), we obtain a general expression for the transverse relaxation rate:

$$R_{2E}^{CP} = \frac{3}{2} C \sum_l P(l) J_0^{(l)\text{lab}}(\omega) \quad (6)$$

where the summation index l specifies the effective motional modes and $P(l)$ is the respective mode amplitude. In the case of collective motions, the spectrum of modes is expected to be continuous, and the summation in equation (6) can be replaced by an integral.

Transverse spin relaxation rates are invariably measured in the laboratory frame, and therefore depend on the spectral densities $J_M^{\text{lab}}(\omega)$ [see equation (4)]. On the other hand, dynamic models are generally defined with respect to local symmetry axes and the respective spectral density functions $J_M^{\text{loc}}(\omega)$ evaluated relative to these axes. The transformation between laboratory and local axis systems leads to a simple expression for the anisotropy of R_{2E}^{CP} .³⁸

$$R_{2E}^{CP} = \frac{3}{2} C \left[\frac{1}{4} (3 \cos^2 \theta_N - 1)^2 J_0^{\text{loc}}(\omega) + 3 \sin^2 \theta_N \cos^2 \theta_N J_1^{\text{loc}}(\omega) + \frac{3}{4} \sin^4 \theta_N J_2^{\text{loc}}(\omega) \right] \quad (7)$$

where θ_N refers to the angle between the static magnetic field and the local axis system. In a powder sample, all values of θ_N are observed, and the relaxation is in general multiexponential. For macroscopically aligned samples, it is possible to measure R_{2E}^{CP} as a function of θ_N and hence determine each of the three $J_M^{\text{loc}}(\omega)$. With this information, it is possible to determine the overall symmetry of the motion, without recourse to any specific model.

Interestingly, equations (5) and (7), describing the dispersion and anisotropy of R_{2E}^{CP} , are qualitatively valid over a dynamic range that extends beyond the limits usually associated with motional narrowing theory.³⁹ However, it should be stressed that these simple expressions are not always suitable, and, when in doubt, it is advisable to use the full numerical approach discussed above.

3 CHARACTERIZATION OF SLOW MOTIONS: TRANSVERSE SPIN RELAXATION IN BIOLOGICAL MEMBRANES

The majority of NMR studies of biological membranes have employed model systems whose composition is well defined and therefore permits more detailed investigations of specific aspects of membrane behavior. In this section, we present an instructive example of the application of NMR transverse spin relaxation methods to study low-frequency molecular dynamics in a biological model membrane. The particular system studied is a dispersion of dimyristoylphosphatidylcholine (DMPC) in water. From a biological point of view, it is the liquid crystalline (L_α) phase of this system that has received most attention. In this phase, the phospholipid molecules arrange in bilayers, separated by water, with the hydrophobic carbon chains oriented towards the center of the bilayer as illustrated in Figure 2. The most commonly employed preparation methods yield dispersions of approximately spherical multilamellar vesicles (see Figure 2). The mean value and variance of the vesicle radius distribution, however, depend significantly on the method of preparation employed.⁴⁰ Alternatively, macroscopically oriented samples can be obtained by incorporating thin layers of the DMPC/water mixture between thin glass plates (see Figure 2).⁴¹

3.1 Multilamellar Vesicles

It was pointed out in the previous section that transverse spin relaxation rates R_{2E}^{CP} depend on the sample orientation, the pulse frequency, and the spin interaction strength. Independent measurement of these three effects, however, is complicated to some extent by the use of vesicle samples. Since multilamellar vesicles are, in effect, isotropic powders, all orientations θ_N are represented, and therefore relaxation is generally multiexponential [see equation (7)]. In principle, it is possible to determine both the anisotropy and the pulse frequency dependence by Fourier transforming the final echoes of CPMG trains for different numbers of echoes, n , at each pulse frequency. This procedure, however, is time and labor-intensive, and alternative methods have usually been employed to extract the desired information. For homogenous samples with a single effective spin label, it is possible to exploit equation (7), so that the measured amplitude $M(2n\tau)$ of the n th echo in a CPMG experiment is

$$M(2n\tau) = M_0 \int_0^1 \exp\left\{-\left[\frac{1}{4}(3\cos^2\theta_N - 1)^2 F_0 + 3\sin^2\theta_N \cos^2\theta_N F_1 + \frac{3}{4}\sin^4\theta_N F_2\right]2n\tau\right\} d\cos\theta_N \quad (8)$$

and the decay curve for a given pulse spacing τ may be fitted by independently varying the three parameters F_0 , F_1 , and F_2 . Although equation (8) is strictly correct only in the motional narrowing limit, where the parameters F_M can be identified with the spectral densities $J_M^{loc}(\omega)$, it may be usefully applied in any regime provided that for each individual orientation θ_N the spins relax monoexponentially.

Figure 3, shows ^{31}P and ^2H scaled transverse relaxation rates, $R_{2E}^{CP}/\Delta\nu^2$ as functions of pulse frequency ω for 2-[14,14,14- d_3]DMPC (see Figure 2) multilamellar vesicles. The ^{31}P relaxation rates were measured using the standard CPMG

pulse sequence with spin lock proton decoupling.⁴² For ^2H , the quadrupolar CPMG sequence¹¹ was employed without proton decoupling. Results are shown for pure DMPC bilayers (open circles), DMPC/4 mol% gramicidin (filled diamonds), and DMPC/40 mol% cholesterol (open triangles), and in each case refer to the $\theta_N = 45^\circ$ orientation, extracted from CPMG echo decays using equation (8). Two important conclusions may be drawn from the results in Figure 3, independently of possible dynamic models. First, the evident frequency dependence of the rates indicates that slow motional processes are responsible for transverse relaxation. Moreover, the fact that the measured dispersion is in all cases approximately given by $R_{2E}^{CP} \propto \omega^{-1}$ suggests a superposition of different modes with frequency components in the 10^2 – 10^5 s^{-1} regime probed specifically in the experiments. The second notable aspect of the results in Figure 3 is that the scaled rates $R_{2E}^{CP}/\Delta\nu^2$ are, to within experimental error, the same for ^{31}P and ^2H . The spectral parameter $\Delta\nu$ is defined as the measured frequency difference between the 0° and 90° singularities in the powder spectra. Thus, $\Delta\nu^2 \propto C$, and we find that the spin-interaction-independent (i.e., purely dynamic) contributions to the relaxation rates for ^{31}P and ^2H are identical. In other words, the lipid headgroup (^{31}P) and the *sn*-2 chain methyl group (^2H) undergo the same low-frequency motions, despite the fact that they are located at opposite extremities of the lipid molecule (see Figure 2). This indicates that the effective dynamic processes are of a mesoscopic nature. In comparing the ^{31}P and ^2H results, it is also worth pointing out that ^{31}P provides markedly superior signal-to-noise ratio and a correspondingly wider dynamic range than ^2H , and there is a good case for proposing ^{31}P as the nucleus of choice for low-frequency dynamics studies of biological membranes.

The results in Figure 3 evaluated for the $\theta_N = 45^\circ$ orientation reflect the most rapidly relaxing component of the multiexponential decay. However, a second slowly relaxing component corresponding to the 90° orientation can also be detected in the ^{31}P CPMG experiments. The scaled ^{31}P relaxation rates are shown in Figure 4. Interestingly, at low frequencies, a plateau appears in the $R_{2E}^{CP}/\Delta\nu^2$ dispersion plot. What is more, the ratios between the plateau values for the different samples are different from the corresponding ratios found for the rapidly relaxing component.

Figure 5 shows the ^{31}P scaled transverse relaxation rates measured for pure DMPC vesicles at four different magnetic fields between 4.7 and 11.7 T. Note that in the case of ^{31}P , it is modulation of the chemical shift anisotropy that is responsible for transverse relaxation. Since the effective chemical shift anisotropy is determined by B_0 ($\Delta\nu \propto B_0$), it follows that the spin interaction strength parameter C also depends on the magnetic field ($C \propto B_0^2$). Thus, if the dynamic behavior of the membrane is unaffected by the presence of magnetic fields, the scaled relaxation rates $R_{2E}^{CP}/\Delta\nu^2$ should be independent of B_0 . The results in Figure 5 show that the higher frequency processes ($\geq 10^3 \text{ s}^{-1}$), monitored by the rapidly relaxing component [Figure 5(a)], are virtually unaffected by the presence of the magnetic field, whereas the low-frequency motions ($\leq 10^3 \text{ s}^{-1}$), reflected by the slowly relaxing component [Figure 5(b)], are apparently suppressed at higher magnetic fields.

NMR studies of slow motions in multilamellar vesicles have focused principally on two types of process, namely lateral diffusion across a curved surface⁸ and collective

Figure 2 Dimyristoylphosphatidylcholine (DMPC) molecule with ^2H and ^{31}P nuclei sites indicated. Also shown are schematic representations of multilamellar vesicles, oriented bilayers, and the collective splay mode for director fluctuations in biological membranes

Results refer to the rapidly relaxing 45° orientation. (b) Scaled ^2H transverse relaxation rates $R_{2E}^{CP}/\Delta\nu^2$ measured for the same samples under the same conditions. Solid lines are included as guides to the eye

orientation fluctuations.^{13,15,43} Both of these mechanisms can be considered mesoscopic in that they involve long-range orientational correlations. In the case of collective motions, a low-frequency cutoff in the relaxation dispersion is expected if long-wavelength fluctuation modes are suppressed. This could arise as a result of the finite size of the particles themselves. Alternatively, magnetic damping of the low-energy modes might occur owing to coupling between the NMR static magnetic field and the anisotropic diamagnetic susceptibility of the vesicles.⁴⁴ Simple models for lateral diffusion over a

Figure 4 Scaled ^{31}P transverse relaxation rates $R_{2E}^{CP}/\Delta\nu^2$ measured as functions of pulse frequency ω for hydrated DMPC (open circles), DMPC/4 mol% gramicidin (filled diamonds) and DMPC/40 mol% cholesterol (open triangles) multilamellar vesicles at 313 K. Results refer to the slowly relaxing 90° orientation. Solid lines are included as guides to the eye

curved surface do not predict such a magnetic-field-dependent low-frequency cutoff. Apparently, the measured $R_{2E}^{CP}/\Delta\nu^2$ dispersion profiles indicate that collective motions play a major role in the relaxation mechanism of multilamellar vesicles. However, the quantitative analysis of these measurements is inevitably limited by the sample heterogeneity. Indeed, it is most likely that the dominant relaxation mechanism depends on the vesicle size and that in any particular sample there may be two or more distinct processes that contribute to the overall measured echo decays.

3.2 Oriented Membrane Samples

The problems associated with the use of multilamellar vesicles for studying membrane dynamics have long been recognized, and alternative methods of sample preparation have been proposed. For example, spherical supported vesicles, prepared by condensing membrane bilayers onto spherical silica beads, have been used to measure lateral diffusion rates of lipid molecules.⁴⁵ The silica beads employed have extremely narrow distributions of radii, and therefore provide virtually monodisperse vesicles. An alternative approach that seeks to avoid the effects of lateral diffusion involves the use of oriented samples.⁴¹ In this case, the membrane bilayers are uniaxially aligned on glass plates such that the bilayer normal and the plate normal are coincident. Lateral diffusion of the molecules no longer induces any angular reorientation of the lipid molecules, and therefore is ineffective as a spin relaxation mechanism for isolated spins such as ^2H or decoupled ^{31}P . Results obtained for oriented DMPC bilayers show R_{2E}^{CP} anisotropies and pulse frequency dispersions consistent with those obtained for multilamellar vesicles, and support the

Figure 5 Scaled ^{31}P transverse relaxation rates $R_{CP}/2E/\Delta v^2$ measured as functions of pulse frequency ω for hydrated DMPC at magnetic fields of 4.7 T (filled circles), 7.0 T (open circles), 9.3 T (filled squares), and 11.7 T (open squares): (a) for the rapidly relaxing 45° orientation; (b) for the slowly relaxing 90° orientation. Solid lines are included as guides to the eye

conclusion that collective motions play a major role in the transverse spin relaxation.^{12,46}

4 EVALUATION OF VISCOELASTIC PROPERTIES: COLLECTIVE ORIENTATIONAL FLUCTUATIONS

Having identified collective motions as a dominant transverse relaxation process, it then remains to apply a suitable

model in order to evaluate the relevant viscoelastic properties. Several hydrodynamic models have been postulated to describe collective orientational fluctuations⁴⁷ and surface undulations¹⁴ in membranes.

4.1 Director Fluctuations

One such model, which has been employed by several groups to interpret transverse relaxation, is based on the concept of director fluctuations.^{12,13,47,48} In liquid crystal terminology, the director $\mathbf{n}$ is defined as the vector describing the orientation of the local phase symmetry axis. It represents the direction of preferred molecular orientation, and in a two-dimensional system such as a membrane may be taken to be normal to the layer surface (see Figure 2). Thermally induced deviations of the director about its average orientation occur, which necessarily modulate the spin interactions of the constituent molecules and hence effect spin relaxation. The director fluctuations may be decomposed into a set of Fourier modes of wavevector q , with mean-square amplitudes $\langle \theta_0^2(q) \rangle$ and exponential decay constants, $\tau(q)$ given by

$$\langle \theta_0^2(q) \rangle = \frac{k_B T}{V K q^2} \quad (9a)$$

$$\tau(q) = \frac{\eta}{K q^2} \quad (9b)$$

where K is an elastic constant, η is an effective viscosity, and V is the volume of the mesoscopic uniform sample. By analogy with models developed for director fluctuations in thermotropic liquid crystals,⁴⁸ K can be identified with the splay elastic constant K_1 , although it has also been suggested that an appropriate quantity for membranes is the curvature elastic modulus $\kappa_c = Kd$, dependent on the bilayer repeat distance d . A more general model for collective motions in membranes, considering bilayer interactions, has been presented recently.⁴⁹

In deriving Equation (9a), it has been assumed that the director fluctuations are of low amplitude. It then follows that the corresponding spectral densities, defined in the average director or local frame, are highly anisotropic in that $J_1^{\text{loc}}(\omega) \gg J_0^{\text{loc}}(\omega)$, $J_2^{\text{loc}}(\omega)$, and, as a first approximation, it is reasonable to retain just $J_1^{\text{loc}}(\omega)$. Combining equations (6) and (7), and replacing the sum over modes l with an integral over the wavevector q , we obtain

$$R_{2E}^{CP} = \frac{27}{8} C \frac{k_B T}{\pi K d} \sin^2 \theta_N \cos^2 \theta_N \times \int_{q_l}^{q_c} \frac{8}{\pi^2} \frac{\tau(q)}{1 + \tau^2(q)(\frac{1}{2}\pi\omega)^2} \hbox{boxd} \ln q \quad (10)$$

The short-wavelength cutoff q_c is governed principally by the molecular dimensions, while the long-wavelength cutoff q_l is related to the size of the effective uniform sample and therefore reflects mesoscopic dimensions. In the case of magnetic damping of collective modes, the long-wavelength cutoff is determined by the magnetic coherence length $\xi = 1/q_l = (K\mu_0/\Delta\chi)^{1/2}(1/B_0)|P_2(\cos \theta_N)|^{-1/2}$, where $\Delta\chi$ is the effective diamagnetic susceptibility anisotropy and μ_0 is the absolute magnetic permeability. The Legendre polynomial $P_2(\cos \theta_N)$ accounts for the orientation dependence of the

Table 1 NMR and Viscoelastic Parameters for Biological Model Membranes at $T = 313$ K

Membrane System	Spectral parameter $\Delta\nu$ (kHz)		Elastic constant ^a K (10^{-11} N)		Effective viscosity ^b η (10^{-3} Pa s)
	³¹ P	² H	³¹ P	² H	
Pure DMPC	5.2	3.5	0.65	0.50	3.0
DMPC/4 mol% gramicidin	4.9	4.8	1.1	1.0	3.5
DMPC/40 mol% cholesterol	5.4	11.7	6.0	6.0	8.0

^a K can be identified with the splay elastic constant K_1 .⁴⁷ A related quantity for membranes is the curvature elastic modulus $k_c = Kd$,¹⁴ dependent on the bilayer repeat distance d .

^bThe viscosity η estimated from the low-frequency cutoff ω_l (see text), based on a diamagnetic susceptibility anisotropy of $\Delta\chi = 1.2 \times 10^{-7}$ SI units.⁵¹

magnetic interaction.⁴⁴ Performing the integration in equation (10) gives

$$R_{2E}^{CP} = \begin{cases} A\omega_l^{-1} & (\omega < \omega_l) \\ A\omega^{-1} & (\omega_c < \omega < \omega_l) \\ A\omega_c\omega^{-2} & (\omega > \omega_c) \end{cases} \quad (11)$$

with

$$A = \frac{27}{2\pi^3} C \sin^2 \theta_N \cos^2 \theta_N \frac{k_B T}{Kd} \quad (12)$$

where $\omega_l = Kq_l^2/\eta = \Delta\chi B_0^2 |P_2(\cos \theta_N)|/\mu_0\eta$ is the low-frequency cutoff and $\omega_c = Kq_c^2/\eta$ is the high-frequency cutoff. Thus, in the intermediate dispersion regime, we find that $R_{2E}^{CP} \propto \omega^{-1}$ and is independent of η . In the low-frequency regime, R_{2E}^{CP} depends on both K and η as well as on B_0 .

4.2 Viscoelastic Parameters

The above expressions account at least qualitatively for the results presented in the previous section. The only obvious point of discrepancy between equation (11) and the experimental results is in the predicted divergence of T_{2E}^{CP} at $\theta_N = 0^\circ$ and $\theta_N = 90^\circ$, although both the oriented sample and the multilamellar vesicles were found to exhibit the correct form for the R_{2E}^{CP} anisotropy. A second-order analysis of director fluctuations^{44,50} yields expressions for $J_0^{loc}(\omega)$ and $J_2^{loc}(\omega)$, and consequently predicts finite T_{2E}^{CP} values at all orientations. A slow motional approach also predicts finite T_{2E}^{CP} at 0° and 90° , and is probably more suitable in the present case. However, the detailed modeling of multiple diffusion process such as director fluctuations in the slow motional regime is far from trivial. For present purposes, we restrict our analysis to the first-order motional narrowing limit expressions. By fitting experimental results, the fast relaxation component (45°) yields values for the elastic constant K of the DMPC membranes. From the low-frequency cutoff of the slow relaxation component (90°), estimates for the effective viscosity η are obtained. The results of the analysis are given in Table 1.

The values obtained for K and η are reasonable, and indicate that transverse spin relaxation is able to provide information concerning viscoelastic properties in biological membranes. Of particular importance from a biological point of view is that the technique may be exploited to investigate modifications of membrane viscoelastic behavior caused by included sterols,

peptides, or proteins. Indeed, the results presented in Table 1 suggest that these effects are by no means small, and invite speculation regarding the consequences for overall membrane function.

1 INTRODUCTION

With the advent of high-field NMR spectrometers and the advances in spectral sensitivity and resolution afforded by the use of isotopically-labeled proteins, it has become possible to study in atomic detail the structural features of unfolded proteins. As long as resolution was limited to that of the proton spectrum, unfolded proteins remained inaccessible to study. However, the spectral dispersion of several of the heteronuclei employed in the labeling of proteins is significantly greater than that of protons, even in the absence of local perturbations caused by different local environments in the folded protein. Thus, for example, the backbone ^{15}N and ^{13}CO chemical shifts of a protein are influenced largely by the amino acid sequence, and are thus of comparable dispersion in unfolded and folded proteins. NMR methods of particular utility in the elucidation of the conformational properties of unfolded and partly folded proteins have recently been reviewed.¹

There are two major reasons to study unfolded proteins. In the first place, a knowledge of the “structure” of the unfolded state is an important pre-requisite for the understanding of the process of protein folding. It is necessary to understand the nature of the starting species before the process can be understood. Secondly, it is becoming clear following the publication of complete genomes that the sequences of many proteins are unlikely to be folded into “normal” globular protein structures.² It is clear from the sequences themselves that the polypeptides must either be unfolded under normal conditions, or else fold into non-globular structures of unknown conformation. It is clear from the large number of such sequences present in the genomes studied so far that these polypeptides must have important, as yet unknown functions, and that the assumption that a folded three-dimensional structure is essential for function needs to be re-examined. The functions of many proteins are dependent on the correct folding of their three-dimensional structure, but numerous proteins, frequently involved in some of the most important regulatory functions in the cell, appear to lack well-defined structure in

the absence of targets or ligands. An understanding of the properties of such proteins will clearly be important in the overall understanding of cellular metabolism.

2 RESONANCE ASSIGNMENTS OF DISORDERED PROTEINS

High-resolution NMR studies of unfolded proteins have been largely enabled by the advent of high-field spectrometers and multidimensional heteronuclear NMR experiments. High sensitivity is a critical factor in the study of unfolded and partly folded proteins, since NMR experiments must often be performed at very low concentration (of the order of 50–300 μM) to prevent protein aggregation.

Compared to the assignment process for folded proteins, resonance assignment for disordered states of proteins presents greater difficulties because of the flexibility of the polypeptide chain, which rapidly interconverts between a large number of conformations. Since the observed chemical shift for a particular resonance is an average over a large number of chemical environments, the chemical shifts of resonances belonging to nuclei in the same residue type are very similar and hard to distinguish from each other. That is, the dispersion of most resonances, especially protons, is poor, with the result that sequence-specific assignment of resonances is difficult. A major advance in the characterization of unfolded states came with the introduction of methods for uniform isotope labeling with ^{13}C and ^{15}N and the development of multi-dimensional triple resonance NMR methods. The backbone ^{15}N and ^{13}CO (carbonyl) resonances are influenced both by residue type and by the local amino acid sequence and therefore remain well-dispersed, even in fully unfolded states.^{3,4} This is illustrated in Figure 1, which shows strips from a series of three-dimensional spectra of unfolded apomyoglobin. In the unfolded state, the dispersion of the $^{13}\text{C}^\alpha$, $^{13}\text{C}^\beta$, H^α , H^β and HN resonances of the alanine residues are virtually identical (Figure 1a and b). The ^{13}CO (Figure 1c) and ^{15}N (not shown) resonances show greater dispersion. An assignment strategy that utilizes the superior chemical shift dispersion of the ^{13}CO resonance in unfolded proteins is especially valuable, given the excellent resolution and long T_2 relaxation time of these resonances.⁵ A set of high resolution constant-time triple resonance experiments utilizing magnetization transfer between sequential ^{13}CO resonances, including those of prolines, have been developed specifically for assignment of unfolded proteins.⁶

The NMR spectra of unfolded proteins have the advantage that the intrinsic flexibility of the polypeptide generally causes the resonances to be much narrower than they would be in a folded protein of similar molecular weight. This characteristic gives special advantages in the implementation of pulse sequences with a large number of delays, which can be rather insensitive for folded proteins of molecular weight greater than 15–20 kDa, due to decay of magnetization during the pulse sequence. For unfolded proteins, however, since T_2 is significantly longer, experiments such as the (HCA)CO(CA)NH⁷ are extremely sensitive and can be utilized with great success.⁸ Unfortunately, partly folded proteins or molten globule states are frequently extremely difficult to study by NMR because their lines are exceptionally broad due to exchange processes on intermediate time scales.

3 USEFUL DIAGNOSTIC NMR PARAMETERS

Since unfolded and partly folded proteins present a manifold of states, it is usually uninformative to attempt the calculation of a solution structure. Instead, a number of NMR parameters can be studied to give information on the relative proportions and nature of residual structure in the protein in a site-specific manner. The values of these parameters for particular residues in the polypeptide chain can build up a picture of the conformational preferences of the protein in the unfolded state. It should always be remembered that unfolded and partly

folded states of proteins are highly dynamic. All parameters are a population-weighted average over all structures in the conformational ensemble. Therefore, conformational preferences must be identified by comparison of experimental NMR parameters to those expected for a random coil state.^{9,10}

3.1 Chemical Shifts

The primary data obtained from resonance assignment for any biomolecule is a set of chemical shift values. Besides identifying the resonances of each amino acid residue in

Figure 1 Comparison of the resonances of the $^{13}\text{C}_\alpha$, $^{13}\text{C}_\beta$, $^1\text{H}_\alpha$, $^1\text{H}_\beta$, ^1HN and ^{13}CO for the 15 alanine residues in apomyoglobin at pH 2.3, 10 mM acetate- d_6 and 5 °C. (Reproduced from Ref.⁵ with permission)

the polypeptide, these values can also give a great deal of information on local conformational preferences of the polypeptide. In the case of unfolded proteins, other NMR parameters may be more sensitive to averaging and less sensitive to small concentrations of structured forms (see below), with the result that the chemical shifts are frequently the best data available to make estimates of conformational preferences.

Since they are least sensitive to the local amino acid sequence, the chemical shifts of $^{13}\text{C}^\alpha$, $^{13}\text{C}^\beta$, and $^1\text{H}^\alpha$ nuclei can provide a convenient and sensitive probe of secondary structural propensities.^{11,12} In addition, the ^{13}CO chemical shift can be used, provided the values are corrected for sequence dependence.¹³ Residues in a completely-folded α -helix have $^{13}\text{C}^\alpha$ and ^{13}CO resonances shifted downfield relative to their

positions in random coil states, while the $^{13}\text{C}^\beta$ and $^1\text{H}^\alpha$ resonances are shifted upfield. The reverse is true for residues in β -strands ($^{13}\text{C}^\alpha$ and ^{13}CO resonances shifted upfield, $^{13}\text{C}^\beta$ and $^1\text{H}^\alpha$ resonances shifted downfield). This is illustrated in Figure 2, which shows the conformational preferences for the unfolded states of two proteins, apomyoglobin at pH 2.3 and apoplastocyanin in low salt at pH 7.0. Preferences for backbone dihedral angles in the α region of (ϕ, ψ) space in some regions of the apomyoglobin sequence are revealed by the secondary chemical shifts, while those of apoplastocyanin reveal an overall propensity for β -structure formation, with a short sequence around residue 60 where (non-native) α -structure propensity is observed.

We wish to stress that these data are extremely sensitive to quite small populations of structured forms, and that the

Figure 2 Secondary chemical shifts, corrected for sequence-dependent contributions, for $^{13}\text{C}^\alpha$, ^{13}CO and $^1\text{H}^\alpha$, for (a) apomyoglobin at pH 2.3, 10 mM acetate- d_6 and 5°C (adapted from Ref.¹⁶ with permission) and (b) apoplastocyanin at pH 6.0, 5 mM KH_2PO_4 , 5 mM β -mercaptoethanol, 35°C . (Adapted from Ref.¹⁷ with permission)

Figure 2 (Continued)

preferences indicated by the plots in Figure 2 are representative of preferences within a conformational ensemble only, rather than well-formed α -helix or β -sheet. This is illustrated in Figure 3, which shows the $^{13}C^\alpha$ secondary shifts for several different folded and partly-folded species of apomyoglobin. It is clear that, while the unfolded form at pH 2.3 shows preferences for α -structure in the sequences corresponding to the A, G and H-helix regions of the folded protein, these secondary shifts are considerably smaller than those in the partly-folded (pH 4) and fully-folded (pH 6) forms.

3.2 Coupling Constants

Coupling constants can in principle provide additional insights into backbone conformational preferences. The most commonly measured coupling constant, $^3J_{HN,H\alpha}$, varies from about 8–10 Hz in β -strands to 4–5 Hz in helix. In disordered proteins, however, conformational fluctuations average the coupling constants and make them insensitive to local structural preferences.⁹ In addition, corrections for residue type and for the nature of the preceding residue are necessary.^{14,15} However, even with such corrections, the $^3J_{HN,H\alpha}$ scalar coupling constants generally provide a very poor diagnostic of residual secondary structure propensities in unfolded proteins.^{16,17}

3.3 Amide Proton Temperature Coefficients and Hydrogen Exchange Rates

Information about hydrogen bonding and solvent interactions can be provided by amide proton temperature coefficients and hydrogen exchange rates.⁹ Temperature coefficients are relatively easy to measure by recording a series of NMR spectra at different temperatures. Values of temperature coefficients normally lie in the range 6–9 ppb K⁻¹. Values lower than this, relative to random coil values, can be an indication of local hydrogen bonded structure and sequestration from solvent. Amide proton exchange rates tend to be very rapid in unfolded proteins because of the presence of completely unfolded members of the conformational ensemble. However, if amide protons protected from exchange are observed, this is a good indication of the presence of structured regions, especially in partly folded proteins and molten globules.¹⁸

3.4 Nuclear Overhauser Effect

The nuclear Overhauser effect (NOE) is the primary source of structural information for folded proteins. It can also be a valuable resource for unfolded and partly folded proteins, but the utility of the NOE is diminished due to the conformational averaging characteristic of these states. Characteristic

Figure 3 Summary of secondary shifts for $^{13}\text{C}\alpha$ for (a) apomyoglobin at pH 2.3, (b) apomyoglobin at pH 4.1, (c) apomyoglobin at pH 6.1, and (d) holomyoglobin (with heme bound) at pH 6.1. (Adapted from Ref.⁸ with permission)

short and medium-range NOEs can be used as a diagnostic of secondary structure preferences.⁹ Sequential $d_{\alpha N}(i, i + 1)$ NOEs are observed in virtually all unstructured states, since the majority populate the β -region of (ϕ, ψ) space.⁹ A propensity for the formation of backbone dihedral angles in the α -region of (ϕ, ψ) space is indicated by the observation of $d_{NN}(i, i + 1)$ NOEs, usually in addition to the $d_{\alpha N}(i, i + 1)$. The observation of both NOE types for a given residue is a strong indication that conformational averaging is occurring; the relative population of dihedral angles in the α and β regions of ϕ, ψ space can be deduced from the intensity ratio of these two NOEs.⁹ It is important to note that the $d_{\alpha N}(i, i + 1)$ and $d_{NN}(i, i + 1)$ sequential NOEs provide information only on local backbone dihedral angle preferences and do not indicate the presence of folded conformations in the absence of additional information, either from medium-range NOEs (e.g., $d_{\alpha N}(i, i + 2)$, $d_{\alpha N}(i, i + 3)$, $d_{\alpha\beta}(i, i + 3)$ NOE connectivities) or from other forms of spectroscopy such as circular dichroism.⁹

The observation of long range NOEs is difficult either for unfolded or partly folded proteins, due to the flexibility of the polypeptide. It requires the presence of a sizeable majority population of a particular folded species before long range NOEs can be observed; so far this has been achieved in only one case.¹⁹

3.5 Paramagnetic Relaxation Probes

With the difficulty of observing long-range NOEs in unfolded and partly folded proteins, it has become necessary to employ a technique of greater sensitivity to detect the presence of transient contacts between distant parts of the polypeptide. This technique relies on the r^{-6} distance-dependent enhancement of nuclear spin relaxation by the unpaired electron in a paramagnetic center, where r is the distance between the unpaired electron and the nuclear spin, and the paramagnetic center is provided by an added spin label such as a nitroxide group. The paramagnetic group can be added to the protein by site-directed mutagenesis to form a cysteine residue, which can be specifically coupled to the nitroxide-bearing moiety. Care must be taken in the interpretation of the results of spin label experiments for unfolded proteins,²⁰ as the presence of conformational averaging is likely to introduce a bias towards those conformations with the shortest contact distances, even though their populations within the ensemble may be quite small. Nevertheless, use of paramagnetic spin label probes can provide exceptionally important insights into the global topology and long-range interactions in unstructured states and partly folded proteins.

4 ESTIMATION OF POLYPEPTIDE CHAIN DYNAMICS

NMR estimates of polypeptide chain dynamics have the potential to provide valuable insights into the internal molecular dynamics and the overall hydrodynamic behavior of unfolded and partly folded states. Local variations in backbone dynamics are correlated with constriction of backbone motions that result from propensities for local interactions of the polypeptide chain.^{8,21} These interactions include formation

Figure 4 Relaxation rates R_1 ($= 1/T_1$) and R_2 ($= 1/T_2$) and heteronuclear NOE for PrP(29–231) at 500 MHz. Sample conditions: 30 °C, pH 5.5 and 0.1 M acetate buffer. (Adapted from Ref.³⁶ with permission)

of local hydrophobic clusters, formation of elements of secondary structure, or long-range tertiary interactions in a partly folded protein or molten globule.

4.1 Measurement of Relaxation Times

To date, the most common method of investigating backbone dynamics is by measurement of ^{15}N T_1 and T_2 relaxation times and the $\{^1\text{H}\}$ - ^{15}N NOE in uniformly ^{15}N -labeled protein, using 2D HSQC-based methods. Optimized pulse sequences have been described.²² If necessary, amino acid specific labeling can be used to obtain additional data in overlapped regions of the spectrum.²¹ Relaxation times and heteronuclear NOEs for unfolded proteins have characteristic values that are quite distinct from those of folded proteins. This can be used to identify regions of flexibility in folded proteins, as shown for example in Figure 4. Values in the two halves of the cellular prion protein PrP^C are quite different. In the N-terminal half of the protein, the NOE and R_2 values are significantly lower than those for the C-terminal half of the protein. In particular, the heteronuclear NOE shows a difference between negative values (N-terminal half) and positive values (C-terminal half), a diagnostic feature distinguishing unfolded protein (N-terminal) from folded (C-terminal).

4.2 Analysis of Relaxation Data

The interpretation of spin relaxation data for folded proteins is commonly performed using the model-free formalism.^{23,24} The dynamics are described in terms of an overall rotational correlation time τ_m , an internal correlation time τ_e , and an order parameter S^2 describing the amplitude of the internal motions.²⁴ These parameters can be interpreted for folded proteins as intuitive physical parameters describing molecular motions. However, the dynamics of unfolded or partly folded proteins are difficult to describe accurately by the model-free approach, because the basic assumption of isotropic tumbling

with a single molecular correlation time is not valid. Nevertheless, qualitative insights into the dynamics of unfolded states have been obtained by model-free analysis.^{25–27}

An alternative approach is to undertake direct mapping of the spectral density either by measurement of additional relaxation parameters²⁸ or by making simplifying approximations.^{29,30} Reduced spectral density mapping gives an interpretation of the dynamics information obtained that depends only upon the accuracy of the experimental relaxation data, in contrast to the assumptions made in model-free analysis, which are of dubious validity for unfolded proteins. The reduced spectral density function, $J(\omega)$, gives information on

Figure 5 Calculated values of $J(0)$, $J(75)$ and $J(653)$ for apomyoglobin, pH 2.3, 25 °C. The horizontal lines show mean values of $J(75)$ (0.19 ns rad⁻¹), $J(653)$ (0.020 ns rad⁻¹), and the 10% trimmed mean value of $J(0)$ (0.97 ns rad⁻¹). Average buried surface area,³⁴ averaged over a seven residue window, is shown together with $J(75)$, with corresponding scale on the right of the figure. (Adapted from Ref.¹⁶ with permission)

the motion of the NH bond vector at three frequencies ω_0 , ω_N and $0.87 \omega_H$. The spectral density function at zero frequency is sensitive both to internal motions on the nanosecond time scale that are faster than the overall tumbling of the protein and to slow motions on the ms- μ s time scale. In contrast, the high frequency spectral densities $J(0.87 \omega_H)$ are sensitive only to fast internal motions, on a picosecond time scale. In the prion protein, nanosecond time scale motions [large $J(0)$ and low $J(0.87 \omega_H)$ values] are dominant for residues with restricted motion, while the reverse is true for more flexible regions of the backbone. The N-terminal region is very flexible, with $J(0)$ values less than 1.5 ns for most residues in the region 29–125. The $J(\omega_N)$ values show less variation with residue number, with typical values between 0.25 and 0.35 ns, although the structured C-terminal part of the protein gives generally higher values. The higher frequency spectral density function $J(0.87 \omega_H)$ has much smaller values (between 0.001 and 0.04 ns), and the trend is opposite to that of $J(0)$, with larger values in the unstructured region and smaller values in the structured region.

4.3 Translational Diffusion Analysis

Further information on the compactness of unfolded states of proteins can be obtained by measurement of the translational diffusion coefficient using the pulsed field gradient water-suppressed longitudinal encode-decode (water-sLED) experiment.³¹ The method can be used to monitor unfolding transitions³² or to measure hydrodynamic radii.^{32,33} The effective dimensions of an unfolded or partly folded protein depend on the extent of local compaction, which is mediated through formation of local hydrophobic clusters or local elements of secondary structure.

4.4 Example of an Application of Spectral Density Mapping

Apomyoglobin unfolded at pH 2.3 provides a good example of the application of spectral density mapping to the elucidation of the local motions in an unfolded protein. The spectral densities of unfolded apomyoglobin¹⁶ are shown in Figure 5. The spectral densities $J(\omega_N)$ ($J(75)$) and $J(0.87 \omega_H)$ ($J(653)$) (Figure 5b and c) are sensitive only to fast (ps-ns) time scale motions. Larger than average values of $J(75)$ are observed in several contiguous regions of the polypeptide chain, Gly5-His12 in the A helix of native myoglobin, Ile28-Lys34 in the B helix, and residues Lys133-Glu148 in the H helix, indicating that motion is somewhat restricted on a sub-ns time scale. Restriction of motions in these regions is confirmed by the observation of lower than average values for $J(653)$. Interestingly, the principal features of the plot of $J(75)$ versus residue number correlate well with the average buried surface area calculated using the parameters of Rose et al.;³⁴ the correlation between $J(\omega_N)$ and hydrophobicity³⁵ is much poorer. Burial of hydrophobic surface area appears to be of major importance in initiation of protein folding.³⁴

The most noticeable features of the $J(0)$ spectral density (Figure 5a) are the greatly increased values in two contiguous segments of the polypeptide, formed by residues Gln8-Ala19, and residues Ile112-His116. The $J(0)$ values in these regions are much larger than expected on the basis of $J(\omega_N)$ and $J(0.87 \omega_H)$ and provide evidence for slow motional processes,

on the ms- μ s time scale. In addition, the NH resonances of Trp14 and Ala15 are broadened beyond detection, an indication that R_2 (and hence $J(0)$) could not be measured but must be very large. A plausible explanation for the broadening of resonances in these two highly localized regions (and nowhere else in the sequence) is that there is some transient (ms- μ s time scale) contact in the acid-unfolded state between the A and G helix regions.¹⁶ These observations provide the first evidence for transient contacts between specific segments of an unfolded polypeptide, and give an indication of the likely mechanism of the earliest collapse steps in the folding of a protein. These data are supported by studies with spin-labeled apomyoglobin (Lietzow, Jamin, Dyson, and Wright, unpublished observations).

5 FUTURE PROSPECTS

The advent of high-field NMR spectrometers and the widespread use of stable isotope labeling has led to an explosion of information on unfolded states of proteins. It is likely that further information will be forthcoming with these and additional new techniques being introduced at the present time. Given the increasing relevance of unfolded states to biologically important systems, including their implication in a number of disease states, we anticipate that the next few years will see a significant increase in the amount of experimental work in this field, and a concomitant increase in our understanding of the nature of unfolded and partly folded states of proteins, as well as of the folding process.

1 INTRODUCTION

Perhaps the most direct observables in NMR spectra are the positions of the resonances, which are generally reported as chemical shifts relative to a standard position. The very existence of useful spectra depends upon chemical shift dispersion, so that nuclei in chemically distinct positions resonate at different frequencies. For peptides and proteins it is convenient to divide the origins of chemical shift differences into two components: the first arises from variations in the local electronic environment, so that aromatic and aliphatic protons, for example, have characteristic shifts that differ from each other and from amide protons. A second component of chemical shift dispersion occurs with nominally identical protons, such as valine H α , due to variations in the nature of adjoining residues and especially to conformational differences in secondary and tertiary structure. While there is no sharp distinction between these two components, the ‘local’ effects usually arise from variations in shielding by electrons in the bonds that contain (or are adjacent to) the resonating nucleus, whereas the longer range effects are generally ‘through-space’ interactions involving functional groups separated by many chemical bonds from the nucleus in question.

This article surveys both empirical trends and theoretical approaches to understanding chemical shift trends in amino acids, peptides and proteins. The main emphasis is on connections between conformation (especially secondary and tertiary structure) and chemical shift. It has been clear for some time that chemical shifts in proteins and peptides depend upon structure in a reasonably regular way, so that, for example, the shifts in structurally homologous proteins are themselves homologous.^{1,2} One force driving recent reexaminations of the origins of chemical shift dispersion has been the rapid growth in the number of protein and peptide assignments. Many of these are now available in a relational database that contains about 140 000 assignments.³ While much of the ‘information content’ of these data remains to be discovered, the following two sections outline some of the clear trends that emerge from surveys of shift distributions

2 EMPIRICAL SURVEYS OF CHEMICAL SHIFTS IN PEPTIDES AND PROTEINS

2.1 Peptides

Short, unstructured peptides provide a useful reference point for many examinations of protein shifts, since they embody most of the local contributions that depend upon the chemical nature of the amino acid side chain, but lack the longer range contributions characteristic of folded proteins. The values most often cited are those of Bundi and Wüthrich (for protons),⁴ and Richarz and Wüthrich (for ¹³C),⁵ based on the peptide H-Gly-Gly-X-Ala-OH, where X represents any of the 20 common amino acids. Table 1 lists these values for the backbone nuclei. It is common practice to define a ‘structural’ shift as the difference between an observed resonance position in a protein or structured peptide and these ‘random coil’ values.

In principle, peptide shifts like these could be computed from first principles using quantum chemistry calculations. At present such calculations are limited to relatively small molecules in the gas phase, and are generally not of routine ‘chemical’ accuracy, at least when one is considering nuclei in different bonding environments.⁶ The situation is changing rapidly, however, and ab initio calculations with reasonable basis sets are now feasible for protein fragments such as amino acids and dipeptides.^{7–11} Such calculations appear to be able to rationalize the dependence of some shifts on backbone dihedral angles, and point the way to the exploration of other effects such as hydrogen bonding and external electric fields. Because a variety of effects are important in influencing shifts, reliable computational studies on amino acids and peptides could have an important impact in the next few years.

2.2 Proteins

The primary empirical study of chemical shifts in proteins is that of Wishart et al.¹² who correlated observed chemical shifts and secondary-structure assignments in over 70 proteins, and computed averages and distributions for shifts in helix, β -strand, and coil configurations. Table 1 gives the results (not sorted by secondary structure) for a larger sample drawn from the BioMagResBank database.³ There are only minor differences between the proton averages given in Table 1 and the earlier results; for the amide ¹⁵N shifts, results for M, P and T differ by more than 1 ppm between the two compilations; for ¹³C α , C, M, N, Q and W differ by at least 1 ppm; the majority of values for the carbonyl ¹³C shift differ by at least this much, perhaps reflecting the small number of available shifts even now. As might be expected, the C α and H α nuclei, which are closest to the side chain, show a strong correlation between the median shift observed in proteins and the ‘random coil’ peptide value: linear correlation coefficients are 0.95 and 0.99 for H α and C α respectively. On the other hand, median shifts in proteins for the amide proton and carbonyl carbon are only weakly related to the peptide random coil shifts, with correlation coefficients of 0.11, and 0.56, respectively. This suggests that longer range interactions, such as hydrogen bonding, may be important in influencing these shifts.

^aData extracted from version 1.0 of the BioMagResBank database.³ For each shift, the first three columns list the number of shifts, the median value and the standard deviation SD about the mean. Column labeled 'rc' gives peptide shifts for H-Gly-Gly-X-Ala-OH from Bundi and Wüthrich⁴ and Richarz and Wüthrich.⁵

3 CHEMICAL SHIFTS AND SECONDARY STRUCTURE

Considerable attention has been paid to ways in which the H α shift reflects local secondary structure. It has been recognized for some time that β -sheet regions show high-frequency shifts for this resonance, while helical regions show low-frequency shifts. In the Wishart et al.¹² survey, the mean H α positions in helices and sheets differ by nearly 0.8 ppm, and there is remarkably little overlap between the two distributions.

The same general trend is found for amide protons, whereas H β shifts move in the opposite direction by a smaller amount. Amide protons at the N-terminus of helices tend to be shifted to high frequency compared with those at the C-terminus. These relationships are in many cases clear enough to drive secondary-structure assignments in proteins,^{13,14} and to gain a qualitative idea of structural differences among homologous systems. It has been shown that this dependence of H α and H β shifts on secondary structure can be explained in terms of peptide group contributions, as outlined below.¹⁵

These ideas may also be of use for linear peptides, where conformational heterogeneity hampers quantitative NOE-based structure calculations. For example, amide proton shifts in model helical peptides are often periodic (with a 3–4 residue repeat pattern);^{16,17} amphipathic helices show a periodic behavior that appears to be related to curving of the helix axis;^{18,19} and it may be possible to characterize helices of marginal stability through an analysis of the solvent dependence of backbone shifts.²⁰

The relationship of ¹⁵N and ¹³C shifts to secondary structure is also of considerable current interest.^{9–12,21} C α and carbonyl shifts exhibit a strong correlation with secondary structure, both moving to higher frequency in helical conformations and to lower frequency in β -strand or extended configurations. As with H α shifts, there is surprisingly little overlap between the distributions, which suggests that reliable conformational conclusions may be drawn, and the C α shift has been used as a site-specific probe of the helix/coil transition in linear peptides.²² There are also indications from solid state studies of peptides that the carbonyl ¹³C resonance moves to higher frequency with decreasing CO $\cdots$ HN hydrogen-bond length,^{23–27} a result that is in rough accord with quantum chemical calculations.²⁶ C β shifts also show systematic differences between helices and sheets, but with much more overlap in the observed distributions.

The situation for amide ¹⁵N shifts in proteins (as with amide protons) is less clear. There are general differences between shifts in helix and sheet structures of about 3 ppm, but the overlap between the two distributions is often greater than this, so that it is difficult to draw simple conclusions from a given set of shifts.^{12,28,29} There is a correlation between amide proton and amide ¹⁵N shifts, suggesting that similar physical effects are influencing both. There is some evidence that ¹⁵N shifts may be periodic in helices, reflecting the local structure, but the relationship does not appear to be a simple one.^{16,30}

4 CHEMICAL SHIFTS AND TERTIARY STRUCTURE

In both organic chemistry and biochemistry, empirical analyses of the effects of ‘distant’ substituents on chemical shifts have played an important role for many years.³¹ There are generally two such types of interaction: magnetic fields arising from anisotropies in the magnetic susceptibilities of distant functional groups, and electric fields created by distant dipoles or charges. The former are strongest with conjugated or partially delocalized electrons (such as in aromatic rings or peptide groups) where there are significant anisotropies in group magnetic susceptibilities.^{32–34} These groups then respond to an external spectrometer field B_0 to create a local magnetic field which can augment or oppose B_0 .³⁵ The electrostatic fields of distant groups influence chemical shifts indirectly, by polarizing chemical bonds, and thus contributing to shielding or deshielding of the nuclei.³⁶ These mechanisms are considered in more detail in the following paragraphs.

4.1 Ring Current Calculations

The general form of empirical theories is $\sigma_{rc} = iBG(\mathbf{r})$ where $\mathbf{r}$ is the vector from the observed proton to the aromatic ring, $G(\mathbf{r})$ is a geometric factor, and i and B are constants.^{31,34} It

is conventional to incorporate in B those constants that would yield the expected contribution from a benzene ring, and to use $i\#$ (the ‘ring current intensity’ factor) to represent the ratio of the intensity expected for the ring in question to that of a benzene ring. There have been several attempts to estimate these factors, based on both quantum mechanical and empirical calculations.^{37,38}

Two commonly used parameterizations of the geometric factors were proposed by Johnson and Bovey³⁹ and by Haigh and Mallion.³⁴ In the latter model, which is one of the simplest to implement, the geometric factor is

$$G(\mathbf{r}) = \sum_{ij} s_{ij} \left\{ \frac{1}{r_i^3} + \frac{1}{r_j^3} \right\} \quad (1)$$

Here r_i and r_j are the distances from ring atoms i and j to the proton, and s_{ij} is the area of the triangle formed by atoms i and j and the proton projected onto the plane of the aromatic ring. The sum is over the bonds in the ring. The Johnson–Bovey model sets up ‘rings’ of current above and below the plane of the atoms, and computes fields from this model. There appears to be very little difference between the two models, except at very short distances.

The heme group is an important special case for ring current calculations, and a variety of empirical calculations have been carried out.^{40–43} A simple model that gives good results treats the heme as five rings: four for the pyrroles, and one ‘macrocycle’ that traverses the large conjugated ring in the canonical valence-bond structure. Cross and Wright⁴³ compared the results of this and other models with a dataset composed of protein and model compound shifts, and Ösapay and Case³⁸ used a larger heme protein database, including cytochromes c , b_5 , and c_{551} and myoglobin. The empirical formulas appear to reproduce the observed behavior quite well.

4.2 Peptide Group Contributions

It has been recognized for some time that the magnetic anisotropy of the peptide group is likely to contribute significantly to chemical shifts in proteins. McConnell³⁵ has shown that when the observed proton and the ‘source’ of the magnetic anisotropy are far apart, the contribution to the local shielding tensor depends upon the magnetic anisotropy of the distant group:

$$\sigma_m = (3L_0R^3)^{-1} \sum_{i=x,y,z} \chi_{ii}(1 - 3\cos^2\theta_i) \quad (2)$$

Here L_0 is the Avogadro constant, R is the distance from the proton to the distant group, χ_{ii} is a component of the magnetic susceptibility tensor, and θ_i is the angle between the i axis and the radius vector $\mathbf{R}$. Since there is no direct method for measuring the magnetic anisotropy of a peptide group within a protein, all estimates of these effects are to some extent empirical. Data for formamide⁴⁴ suggest that the peptide group is nearly axially symmetric about the out-of-plane axis, with an anisotropy $\Delta\chi$ of $-5.1 \pm 0.6 \times 10^{-6}$ erg (G²-mol)⁻¹. This value is in good agreement with the one obtained using an empirical theoretical approach developed by Pauling.³³ -5.4×10^{-6} erg (G²-mol)⁻¹.

Alternative models for peptide groups can be constructed by adding contributions from individual atoms⁴⁵ or bonds,^{46–48} rather than using parameters for the peptide group as a whole. These alternative methods give generally similar results.^{49,50}

Contributions from peptide groups calculated in this way can explain to a large extent the observed behavior of $H\alpha$ chemical shifts as a function of local secondary structure.¹⁵ Because of the R^{-3} distance dependence in equation (2), the neighboring peptide groups have the greatest influence, so that the shift depends to a large extent on the backbone dihedral angles ϕ and ψ , which determine the geometric relationship between the peptide planes and the $H\alpha$ position.

4.3 Electrostatic Contributions

A significant contribution to chemical shifts can also arise from distant charges and dipoles, which can polarize the C–H bond and thereby increase or decrease the local shielding by electrons. The most significant term is expected to be proportional to the projection of the local electric field onto the C–H vector:

$$\sigma_{\text{el}} = AE(\text{C-H}) \quad (3)$$

Buckingham³⁶ suggested that an appropriate value for A would be $-2 \times 10^{-12} \text{ esu}^{-1}$, but this magnitude clearly depends upon the way in which local electric fields are estimated. Most estimates to date have been based on Coulomb's law using partial charge models from molecular mechanics force fields, but this approach ignores important solvent effects that screen charge interactions, and further work in this area is needed.

The relative importance of various contributions is expected to be different for protons than for heavier nuclei. Ring current and magnetic anisotropy contributions will contribute the same absolute shift for all nuclei, and hence should be less important for nuclei like ^{13}C or ^{15}N that have large chemical shift ranges (compared with protons). These heavier nuclei, on the other hand, are more sensitive to electrostatic effects than are protons, probably because of the ability of electric fields to polarize their occupied p shells, which are unoccupied for hydrogen,⁵¹ and some interesting attempts have been made to correlate shifts in proteins with estimates of the local electric fields.^{52,53}

The analysis of chemical shift patterns using these ideas has a long history in organic chemistry.^{31,34,46} Recently, several groups have shown that such calculations can explain a large portion of the chemical shift dispersion seen in globular proteins.^{38,47,48,54,55} For example, Ösapay and Case³⁸ analyzed proton shifts from 17 proteins whose X-ray crystal structures had been determined; for 5678 protons bonded to carbon they obtained a linear correlation coefficient of 0.88 between the calculated and observed structural shifts, with an rms error of 0.23 ppm; for side-chain protons in nonheme proteins the rms error was 0.18 ppm, and for methyl groups it was 0.13 ppm. Computer codes that implement these ideas are available from the author, and equivalent code is part of the AMBER molecular modeling package, which also allows refinement of structures using penalty functions based on chemical shift formulas.⁵⁶ Initial applications to myoglobin⁵⁷ suggest that this idea may be a feasible and useful approach.

5 CONCLUSIONS

There is little doubt that the use of chemical shift information for peptides and proteins will continue to grow as a source of structural information. The $H\alpha$ and $C\alpha$ shifts appear to provide a reliable indicator of local secondary structure, and useful theories are available for magnetic interactions with aromatic rings and peptide groups. Electrostatic interactions (including hydrogen bonding and solvation effects) are less well understood. Ab initio electronic structure calculations are beginning to address problems of interest to peptide and protein chemists, and this, together with empirical analyses of larger numbers of shifts, should provide new insight into the origins of chemical shift dispersion.

1 INTRODUCTION

NMR spectroscopy affords a unique and powerful analytical tool which can be used to investigate matter in its various states, particularly inasmuch as it provides information pertinent to both average and dynamical properties. By contrast, with reference to disordered systems, X-ray and neutron-scattering techniques yield information of a relatively low-resolution nature, and atomic level data are not obtained. Because NMR spectroscopy provides knowledge at the microscopic level regarding liquid crystalline materials, it plays a unique and vital role in their investigation. The application of NMR methods to membrane bilayers builds upon the following: ^1H NMR studies by the groups of Bloom,¹ Chan,²⁻⁴ and Klein;⁵ the introduction of ^2H NMR spectroscopy by Seelig and co-workers;⁶ natural abundance ^{13}C NMR studies by the group of Metcalfe;⁷ and finally the ground-breaking EPR spin label work of McConnell and colleagues.^{8,9}

It is known that biomembranes comprise a bilayer of lipids, containing proteins which span the bilayer or are associated with the aqueous interface. In the biologically relevant liquid crystalline phase, the constituents of membranes are highly disordered, and considerable motion occurs. The lipid bilayer represents the fundamental permeability barrier to the passage of ions and polar molecules, whereas the distinctive functions of biological membranes are carried out by proteins. In this contribution we briefly describe the advances made during the past few decades in the application of ^2H and ^{13}C NMR methods to the investigation of lipid bilayers in the fluid (L_α)

phase. (i) First we review multinuclear MR lineshape studies of lipid bilayers; (ii) the use of ^2H and ^{13}C NMR relaxation methods is described as a means of obtaining information regarding the spectral densities of motion and dynamical properties of liquid crystalline materials; and, finally, (iii) we provide a summary of the application of NMR relaxation methods to lipid bilayers in the liquid crystalline phase.

2 IRREDUCIBLE REPRESENTATION OF THE NUCLEAR SPIN HAMILTONIAN

With regard to molecular solids and liquid crystalline materials, the information provided by NMR spectroscopy includes the motionally averaged NMR lineshapes due to the dipolar, quadrupolar, or chemical shift tensors, together with the relaxation rates which are due to fluctuations of the tensors about their equilibrium values. The above information is manifested in the correlation functions $G_m(t)$ corresponding to the various second-rank quantities, i.e. the dipolar, quadrupolar, or chemical shift tensors, or equivalently their Fourier transform partners, the spectral densities $J_m(\omega)$. By combining lineshape and relaxation studies one can gain considerable insight regarding equilibrium and dynamical properties of bilayers. How can liquid crystalline bilayers be investigated at the molecular and atomic levels?

In general, the coupling of a spin $I = 1$ system is described by the Hamiltonian operator¹⁰

$$\hat{\mathcal{H}}_\lambda = C_\lambda \sum_{m=-2}^2 (-1)^m \hat{T}_{-m}^{(2)\text{lab}} V_m^{(2)\text{lab}} \quad (1)$$

where C_λ is a constant and λ refers to a specific interaction, e.g. the dipolar (D) or quadrupolar (Q) coupling. All symbols have their customary meanings, where $\hat{T}_m^{(2)}$ and $V_m^{(2)}$ are second-rank irreducible spherical tensors, corresponding to the nuclear spin angular momentum operators $\hat{\mathbf{I}}$ and the coupling tensor $\mathbf{V}$, respectively. The spin angular momentum is quantized in the main external magnetic field (denoted 'lab'), where the corresponding irreducible tensor operators are defined by¹¹

$$\hat{T}_0^{(2)\text{lab}} = \sqrt{\frac{1}{6}} (3\hat{I}_Z\hat{S}_Z - \hat{\mathbf{I}} \cdot \hat{\mathbf{S}}) \quad (2a)$$

$$\hat{T}_{\pm 1}^{(2)\text{lab}} = \mp \frac{1}{2} (\hat{I}_Z\hat{S}_\pm + \hat{I}_\pm\hat{S}_Z) \quad (2b)$$

$$\hat{T}_{\pm 2}^{(2)\text{lab}} = \frac{1}{2} \hat{I}_\pm\hat{S}_\pm \quad (2c)$$

in which $\hat{I}_\pm \equiv \hat{I}_X \pm i\hat{I}_Y$ and likewise for $\hat{S}_\pm$. (For the heteronuclear magnetic dipolar coupling $\hat{\mathbf{I}} \neq \hat{\mathbf{S}}$; whereas for the homonuclear dipolar coupling or the electric quadrupolar coupling $\hat{\mathbf{I}} = \hat{\mathbf{S}}$.) By contrast, the irreducible components of the coupling tensor $V_m^{(2)}$ are expressed in a molecule-fixed principal axis system (PAS) as discussed by Häberlen¹¹ and Spiess:¹⁰

$$V_0^{(2)\text{PAS}} = \sqrt{\frac{3}{2}} \delta_\lambda \quad (3a)$$

$$V_{\pm 1}^{(2)\text{PAS}} = 0 \quad (3b)$$

$$V_{\pm 2}^{(2)\text{PAS}} = -\frac{1}{2} \delta_\lambda \eta_\lambda \quad (3c)$$

Dipolar coupling:	Quadrupolar coupling ($I=1$):
$C_D = -2\gamma_I\gamma_S\hbar$	$C_Q = eQ/2\hbar$
$\delta_D = \langle r_{IS}^{-3} \rangle$	$\delta_Q = eq$
$\eta_D = 0$	η_Q

Note that the above irreducible tensors are expressed in different coordinate frames; the spin operators $\hat{I}$ and $\hat{S}$ correspond to the laboratory frame defined by the main magnetic field, whereas the dipolar or quadrupolar couplings involve the molecule-fixed frame. To express the Hamiltonian in a single frame, e.g. that of the laboratory, one must employ the transformation properties of irreducible tensors under rotations.¹⁵ The irreducible components of the coupling tensor in the laboratory frame and the principal axis system are related by

In the above expression, $\Omega_{\text{PL}} = (\alpha_{\text{PL}}, \beta_{\text{PL}}, \gamma_{\text{PL}})$ are the Euler angles which describe active transformation¹⁵ of the irreducible components from the principal axis system (P) to the laboratory frame (L). The definitions of Brink and Satchler¹⁵ are used for the Wigner rotation matrices, $D_{m'm}^{(j)}(\Omega) = e^{-im'\alpha} d_{m'm}^{(j)}(\beta) e^{-im\gamma}$; where (m', m) are generalized projection indices, j is the angular momentum, $\Omega \equiv (\alpha, \beta, \gamma)$ are generalized Euler angles, and the elements of the reduced rotation matrix are indicated by $d_{m'm}^{(j)}(\beta)$. [Note that $D_{00}^{(j)}(\Omega) = d_{00}^{(j)}(\beta) = P_j(\cos \beta)$, where P_j is a Legendre polynomial of rank j .]

$$D_{sm}^{(2)}(\Omega_{\text{PL}}; t) = \sum_r \sum_q \sum_p \sum_n D_{sr}^{(2)}(\Omega_{\text{PI}}; t) D_{rq}^{(2)}(\Omega_{\text{IM}}; t) D_{qp}^{(2)}(\Omega_{\text{MN}}; t) D_{pn}^{(2)}(\Omega_{\text{ND}}; t) D_{nm}^{(2)}(\Omega_{\text{DL}}) \quad (5)$$

director ($\mathbf{D}$) to the laboratory frame ($\mathbf{L}$) corresponding to the static external magnetic field. In the last transformation the spherical polar angles characterizing the orientation of the magnetic field within the frame of the bilayer are denoted by $(\alpha_{\text{DL}}, \beta_{\text{DL}}) \equiv (\phi, \theta)$. The Euler angles describing the various transformations may be either time-dependent as in Figure 1 or fixed; whereas the Ω_{DL} transformation is fixed. The expansion, equation (5), can be further generalized to encompass an arbitrary number of transformations; alternatively, closure enables those transformations not relevant for a given motional description to be collapsed.¹⁶

Now in general the transition frequencies are governed by the eigenvalues of the motionally averaged Hamiltonian, in which secular terms ($m = 0$) are considered. For the different models investigated, the observed lineshape is dependent on the equilibrium distribution of the tensor orientations. In the case of ^2H NMR the coupling is due to the quadrupolar interaction of the ^2H nucleus with the electric field gradient of

Figure 1 Schematic illustration of transformations employed in dynamical models for membrane constituents as described in the text

the chemical bond. One can then write that

$$\langle \nu_Q^\pm \rangle = \pm \frac{3}{4} \chi S_{CD} D_{00}^{(2)}(\Omega_{DL}) \quad (6)$$

where the doublet components $\nu_Q^\pm$ are separated by the quadrupolar splitting, $\Delta \nu_Q \equiv \nu_Q^+ - \nu_Q^-$, and the angular brackets denote a time or ensemble average. The segmental C–²H order parameter is then defined by

$$S_{CD} \equiv \langle D_{00}^{(2)}(\Omega_{PD}) \rangle = \frac{1}{2} \langle 3 \cos^2 \beta_{PD} - 1 \rangle \quad (7)$$

A similar formalism can be used for the homonuclear dipolar interaction in the case of ¹H NMR, and the heteronuclear ¹³C–¹H dipolar interaction in the case of ¹³C NMR spectroscopy.

3 NMR LINESHAPES FOR DIPOLAR AND QUADRUPOLEAR INTERACTIONS

3.1 Proton NMR Spectroscopy

In order to obtain information about residual anisotropic interactions, e.g. dipolar interactions, it is necessary to study unsonicated bilayer systems. Perhaps the simplest approach entails investigation of the ¹H NMR spectral lineshapes.^{1–3,22} Due to lateral self-diffusion of the lipids, the intermolecular ¹H–¹H dipolar interactions are averaged to zero,¹ and one observes the intramolecular part. However, because the motions are restricted in their angular range, one still has dipolar interactions among the different groups on the chain and between the two acyl chains, so that pairwise dipolar couplings are not resolved.^{1–3,22} In this case the moments of the lineshapes contain useful information, and can be analyzed in terms of a superposition of dipolar order parameters corresponding to the various ¹H–¹H pairs.¹ (See also *Bilayer Membranes: Proton and Fluorine-19 NMR*.)

One avenue to simplification is to study small sonicated vesicles where the rapid tumbling averages the dipolar interactions to zero. Here the lineshape is due to modulation of the residual dipolar couplings by the overall vesicle reorientation.^{1,22} Alternatively, one can employ magic angle spinning (MAS) to narrow the spectral lines.²³ But in either case knowledge of the residual dipolar interactions may be difficult to extract in a model-free manner,^{4,24} and there may be influences due to curvature of the interface.^{2,25} Another strategy involves complete deuteration of the lipid molecule, with the exception of individual proton–proton pairs, which is a challenging synthetic task. However, a simpler alternative is to recognize that the Hamiltonian for the quadrupolar interaction of the ²H nucleus is isomorphous to the pairwise dipolar interaction between like spins; both comprise spin $I = 1$ systems! It is synthetically much easier to incorporate deuterium into a lipid than to deuterate the entire molecule.

3.2 Deuterium NMR Spectroscopy

In discussing NMR observables in relation to the equilibrium and dynamical properties of bilayers, it is useful to focus

Figure 2 Representative ²H NMR spectrum (de-Paked) of a multilamellar dispersion of 1-perdeuteropalmitoyl-2-docosa-hexaenoyl-*sn*-glycero-3-phosphocholine (PDPC) obtained at 55.4 MHz and 30 °C in the liquid crystalline (L_α) phase

on ²H NMR spectroscopy.^{6,26} Here the electric quadrupolar interaction is by far the largest coupling, and dominates over the chemical shift or homo- or heteronuclear dipolar interactions. The great value of ²H NMR is that one can study the properties of an isolated spin $I = 1$ system without the complication of additional interactions of comparable magnitude. Moreover, as noted above, the quadrupolar interaction is isomorphous to the dipolar coupling, so that the formalism and conceptual approach can be extended to other nuclei such as ¹H and ¹³C.

Figure 2 depicts a representative ²H NMR spectrum of a lipid bilayer in the fluid, liquid crystalline state.^{27,28} If all the segments were equivalent then a single quadrupolar splitting would be observed. However, this is clearly not the case; rather, a family of splittings is found which indicate variations in motional averaging among the different chain segments. Although the static quadrupolar coupling is the same everywhere along the chain, the residual quadrupolar couplings of the various segments are clearly inequivalent. Now for significant motional averaging to occur the rate of the fluctuations must be greater than about $9\chi/8 = 1.9 \times 10^5 \text{ s}^{-1}$, corresponding to the full angular anisotropy of the single quantum transitions of the $I = 1$ nucleus. It is remarkable that well-defined residual quadrupolar interactions are observed, corresponding to the order parameters S_{CD} of the various chain segments.⁶ The ²H NMR spectrum clearly shows that the system can be quite fluid and still give rise to distinct quadrupolar splittings. Thus, one obtains information at the atomic level in the disordered, liquid crystalline state. (See also *Membranes: Deuterium NMR*.)

3.3 Carbon-13 NMR Spectroscopy

When the motion is restricted, so that the magnetic dipolar, chemical shift, or electric quadrupolar tensors are not averaged to their traces, then considerable broadening of the spectral lines occurs. Thus, natural-abundance ¹³C NMR spectra of

unsonicated bilayer membranes are dominated by unresolved homo- and heteronuclear dipolar interactions, together with the anisotropic chemical shift of the ^{13}C nucleus.²⁰ As in the case of ^1H NMR, the dipolar and chemical shift tensors can be averaged to their traces by investigating small sonicated vesicles; well-resolved ^{13}C NMR spectra are then obtained.⁷ However, information regarding the averaged tensors is difficult to retrieve, and one is largely confined to relaxation studies.^{17,18} (See also *Sonicated Membrane Vesicles*.)

An alternative is to remove the chemical shift anisotropy and ^{13}C – ^1H dipolar interaction by MAS; high-power dipolar decoupling is unnecessary in the fluid, liquid crystalline phase.^{20,23,29} Figure 3 shows representative natural-abundance MAS ^{13}C NMR spectra of 1,2-dilauroyl-*sn*-glycero-3-phosphocholine (DLPC) (Figure 3a) and a mixture of 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC)/cholesterol (1:1) (Figure 3b), each in the fluid phase.^{20,30} The isotropic chemical shifts of both the flexible phospholipids as well as the rigid cholesterol moiety are readily detected.³⁰

Figure 3 Magic angle spinning (MAS) natural abundance ^{13}C NMR spectra at 50 MHz of multilamellar dispersions of (a) DLPC at ambient temperature, and (b) DPPC/cholesterol (1:1) at 50 °C in the liquid crystalline phase. Resonances are denoted; C refers to cholesterol

These results clearly illustrate the utility of MAS methods for NMR studies of disordered lipid bilayer systems, as well as other liquid crystalline systems and soft matter in general. (See also *Magic Angle Spinning*.)

One can then reintroduce the dipolar interaction^{20,30} or the chemical shift anisotropy (CSA)³¹ selectively by implementation of two-dimensional NMR techniques. Heteronuclear dipolar interactions can be included by applying WAHUA¹¹ or other suitable pulse sequences for decoupling of the homonuclei during the evolution period t_1 , with MAS during the acquisition period t_2 to obtain dipolar–chemical shift NMR spectra.^{20,30} Alternatively, modulation due to the chemical shift anisotropy can be included during the evolution period t_1 by variable angle hopping, followed by MAS during t_2 to yield CSA–chemical shift ^{13}C NMR spectra.³¹ These natural-abundance ^{13}C NMR methods provide a potentially rich source of knowledge about the average structural properties of lipid bilayers. Such approaches have the advantage that information regarding the entire lipid molecule is obtained without isotopic labeling, but they have the drawback that appreciable spectral overlap occurs within the acyl carbon region (Figure 3). However, by combining the results of ^2H NMR with ^{13}C NMR spectroscopy of lipid bilayers one can obtain considerably more information than with either technique alone! (See also *Membranes: Carbon-13 NMR*.)

3.4 Order Profiles from Deuterium and Carbon-13 NMR Spectroscopy

In the case of ^2H NMR spectroscopy the information content can be reduced to a profile of the order parameters $S_{\text{CD}}^{(i)}$ as a function of chain position (index i).^{6,32} Such a representative plot of the order parameters versus the chain position is shown for 1,2-diperdeuterolauroyl-*sn*-glycero-3-phosphocholine (DLPC- d_{46}) in Figure 4(a). The order profile comprises a plateau in the $S_{\text{CD}}^{(i)}$ values over the first part of the chains, followed by a decrease as the chain terminus is approached. The plateau in the order profile is associated with tethering of the acyl chains to the aqueous interface. It follows that beyond the plateau region the segments are more disordered to fill in the free volume that would otherwise be present, i.e. to maintain the density constant at essentially that of liquid hydrocarbon. Analogous ^2H NMR studies of phospholipids have been carried out for lipids in other physical states, including the normal hexagonal (H_I) and reverse hexagonal (H_II) phases.^{25,33,34} (See also *Lipid Polymorphism*.) In the case of ^{13}C NMR spectroscopy, order parameters, S_{CH} , are obtained by comparing the residual dipolar or chemical shift tensors to their static values, and yield good agreement with previous ^2H NMR results.^{20,31}

4 NUCLEAR SPIN RELAXATION

In the fluid L_α phase, dynamical information can be obtained from measurement and interpretation of the nuclear spin relaxation rates.¹⁴ Analysis of the relaxation enables one to disentangle the various types of motions which lead to the averaging of the dipolar, quadrupolar, or chemical shift tensors. Early ^1H NMR^{2,5} and ^{13}C NMR⁷ relaxation

Figure 4 Profiles of (a) segmental order parameters, $S_{CD}^{(i)}$, and (b) spin-lattice relaxation rates, $R_{1Z}^{(i)}$, as functions of acyl segment position (i) for DLPC- d_{46} oriented on planar substrates at 46.1 MHz and 40 °C in the liquid-crystalline phase. ●, $sn-1$ chain; ○, $sn-2$ chain. (Reproduced by permission of the American Institute of Physics from T. P. Touard, T. M. Alam, and M. F. Brown, *J. Chem. Phys.*, 1994, **101**, 5229)

rate studies provided evidence for a liquid-like mobility of the chains; however, separation of the contributions from the statistical ordering and rate of motions² was not always considered.

As shown by Brown, Seelig, and Häberlen,³⁵ a profile is seen in the 2H NMR relaxation rates as a function of chain position, which is markedly reminiscent of the profile seen for the 2H NMR order parameters. A representative 2H NMR relaxation profile for DLPC- d_{46} is shown in Figure 4(b). As can be seen, the $R_{1Z}^{(i)}$ profile parallels the order profile in that a plateau is observed over the initial part of the chain, followed by a decrease in the $R_{1Z}^{(i)}$ relaxation rates as the acyl chain terminus is approached. Similar relaxation profiles are obtained for the ^{13}C R_{1Z} values of small vesicles,¹⁸ as well as the R_{1Z} and $R_{1\rho}$ values of unsonicated bilayer membranes.²⁰ It is noteworthy that few differences exist between the R_{1Z} rates of unsonicated bilayers and small vesicles.³⁵ The relaxation profile can be due to a profile of the motional amplitudes along the chains, or alternatively it can represent the rate of motion along the chains, viz. as a function of depth within the bilayer hydrocarbon region. Which of the above interpretations is correct?

Moreover, an inherent feature of the nuclear spin relaxation is that there is a characteristic frequency (magnetic field strength) dependence.^{17–19, 36} This was first extensively investigated by Chan and co-workers;¹⁷ representative 1H

Figure 5 Proton spin-lattice relaxation rates R_{1Z} for acyl segments of DPPC vesicles in the liquid crystalline state versus reciprocal temperature at two different frequencies (magnetic field strengths); ○, DPPC; ▲, DPPC/DPPC- d_{62} (2:8); ●, DPPC/DPPC- d_{62} (1:9). The results indicate the presence of both intermolecular and intramolecular contributions. (Reproduced by permission of Elsevier Science Publishers from P. A. Kroon, M. Kainosho, and S. I. Chan, *Biochim. Biophys. Acta*, 1976, **433**, 282)

NMR data from their work for DPPC at two different frequencies are shown in Figure 5. The frequency dependence of the relaxation suggests that slow motions of the lipids occur within the bilayer, which are not found in simple fluids. These experiments paved the way for subsequent investigations of the relaxation frequency dependence using ^{13}C and 2H NMR techniques.^{18,19} In addition, investigations involving magnetic field cycling have provided further valuable knowledge of the relaxation frequency dependence.²¹ (See also **Field Cycling Experiments**.)

Let us take a closer look at what can be learned from combined NMR lineshape and relaxation studies. One can apply the Bloch–Wangsness–Redfield treatment of the density matrix³⁷ to the relaxation of lipid bilayers,³⁸ in which fluctuations of the nuclear coupling with its environment yield a time-dependent perturbation. (See also **Relaxation Theory: Density Matrix Formulation**.) The residual or time-averaged Hamiltonian $\langle \hat{\mathcal{H}}_\lambda \rangle$ is subtracted from the time-dependent Hamiltonian to yield the fluctuating part $\hat{\mathcal{H}}'_\lambda(t)$, which is given by^{2,35}

$$\hat{\mathcal{H}}'_\lambda(t) \equiv \hat{\mathcal{H}}_\lambda(t) - \langle \hat{\mathcal{H}}_\lambda \rangle \quad (8)$$

Correlation functions of the coupling Hamiltonian can then be written as

$$G_{\alpha\beta\alpha'\beta'}(t) = \langle (\alpha | \hat{\mathcal{H}}'_\lambda(0) | \beta) (\beta' | \hat{\mathcal{H}}'_\lambda(t) | \alpha') \rangle \quad (9)$$

The Dirac bra-ket notation ($| \rangle$ and $\langle |$) is used, where α , α' , β , and β' correspond to the eigenstates of the spin system, and the angled brackets indicate a time or ensemble average. Substituting for the Hamiltonian $\hat{\mathcal{H}}'_\lambda(t)$, one obtains for the correlation functions due to the fluctuating part

$$G_{\alpha\beta\alpha'\beta'}(t) = \frac{3}{2}\delta_\lambda^2 C_\lambda^2 \sum_m (\alpha|\hat{T}_{-m}^{(2)\text{lab}}|\beta)^* (\alpha'|\hat{T}_{-m}^{(2)\text{lab}}|\beta') G_m(t) \quad (10)$$

Now according to equation (10) the correlation functions contain products of the matrix elements of the irreducible tensor operators due to the angular momentum, as well as the irreducible correlation functions $G_m(t)$ which describe fluctuations of the coupling tensor. The matrix elements encompass the selection rules and characterize the allowed transitions; whereas the correlation functions $G_m(t)$ describe the time dependence of the fluctuating irreducible components about their mean values. (It can be shown using group theoretical procedures that cross-correlation terms involving different values of the projection index m vanish rigorously for the case of cylindrical symmetry.)

The correlation functions $G_m(t)$ can be written as

$$G_m(t) = \langle [V_m^{(2)\text{lab}}(0) - \langle V_m^{(2)\text{lab}} \rangle] [V_m^{(2)\text{lab}}(t) - \langle V_m^{(2)\text{lab}} \rangle] \rangle / [V_0^{(2)\text{PAS}}]^2 \quad (11)$$

For $\eta_\lambda = 0$ only the $V_0^{(2)\text{PAS}}$ irreducible component is nonzero, so that one obtains^{39,40}

$$G_m(t) = \langle D_{0m}^{(2)*}(\Omega_{\text{PL}}; 0) D_{0m}^{(2)}(\Omega_{\text{PL}}; t) \rangle - |\langle D_{0m}^{(2)}(\Omega_{\text{PL}}) \rangle|^2 \quad (12)$$

In general, however, one needs to consider cross terms involving the symmetric (δ_λ) and asymmetric (η_λ) components of the coupling tensor.⁴¹ The corresponding irreducible spectral densities are the Fourier transform partners of the correlation functions, $G_m(t)$, and are given by

$$J_m(\omega) = \text{Re} \int_{-\infty}^{\infty} G_m(t) e^{-i\omega t} dt \quad (13)$$

The spectral densities $J_m(\omega)$ describe the density of the fluctuations at the frequency ω , which produce the observed nuclear relaxation. In what follows, it is useful to introduce the following coupling constants:

$$\chi_D \equiv (\gamma_I \gamma_S h / 2\pi^2) \langle r_{IS}^{-3} \rangle \quad (14a)$$

$$\chi_Q \equiv e^2 q Q / h \quad (14b)$$

4.1 Proton and Deuterium NMR Spectroscopy

For the case that $\hat{I} = \hat{S}$, e.g. due to the pairwise magnetic dipolar interaction between ^1H nuclei or the electric quadrupolar interaction of the ^2H nucleus, one obtains for the various relaxation rates

$$R_{1Z} \equiv \frac{1}{T_{1Z}} = \frac{3}{4} \pi^2 \chi^2 [J_1(\omega_I) + 4J_2(2\omega_I)] \quad (15a)$$

$$R_{1D}, R_{1Q} \equiv \frac{1}{T_{1D}}, \frac{1}{T_{1Q}} = \frac{9}{4} \pi^2 \chi^2 J_1(\omega_I) \quad (15b)$$

$$R_2 \equiv \frac{1}{T_2} = \frac{3}{8} \pi^2 \chi^2 [3J_0(0) + 3J_1(\omega_I) + 2J_2(2\omega_I)] \quad (15c)$$

Here χ is the coupling constant for the dipolar or quadrupolar interaction, i.e. $\chi \equiv \chi_D$ or χ_Q ; ω_I is the nuclear Larmor frequency; and $J_m(\omega_I)$ are the spectral densities of motion. The relaxation rate for the longitudinal or Zeeman magnetization (i.e. the spin-lattice relaxation rate) is denoted by R_{1Z} , where T_{1Z} is the corresponding relaxation time. The rates for the decay of dipolar order and the decay of quadrupolar order are denoted by R_{1D} and R_{1Q} , respectively, with relaxation times T_{1D} and T_{1Q} . Finally, the relaxation rate for the decay of transverse single quantum coherence (i.e. the spin-spin relaxation rate) is denoted by R_2 , where the relaxation time is T_2 . The cylindrical symmetry about the bilayer normal (director axis) means in general that the irreducible spectral densities depend on the projection index m . In systems undergoing isotropic averaging, e.g. phospholipid vesicles, the dependence on the m index vanishes due to the spherical symmetry, such that $J_m(\omega_I) \rightarrow \langle J_m(\omega_I) \rangle \equiv J(\omega_I)$.

One should note that, as indicated above, R_2 corresponds to the transverse relaxation rate in ordered media, where the $|+1\rangle \rightarrow |0\rangle$ and $|0\rangle \rightarrow |-1\rangle$ single quantum transitions are typically nondegenerate.³⁸ In systems undergoing isotropic averaging, the transverse cross-relaxation rate must also be included, yielding

$$R_2 = \frac{3}{8} \pi^2 \chi^2 [3J(0) + 5J(\omega_I) + 2J(2\omega_I)] \quad (16)$$

(See also *Deuteron Relaxation Rates in Liquid Crystalline Samples: Experimental Methods Liquid Crystalline Samples: Deuterium NMR*.)

4.2 Carbon-13 NMR Spectroscopy

For $\hat{I} \neq \hat{S}$, e.g. the $^{13}\text{C}-^1\text{H}$ direct magnetic dipolar interaction, the various observables are given by⁴²

$$R_{1Z} \equiv \frac{1}{NT_{1Z}} = \frac{3}{2} \pi^2 \chi_D^2 \left[\frac{1}{6} J_0(\omega_S - \omega_I) + \frac{1}{2} J_1(\omega_I) + J_2(\omega_S + \omega_I) \right] \quad (17a)$$

$$\eta_{IS} = \left(\frac{\gamma_S}{\gamma_I} \right) \frac{-\frac{1}{6} J_0(\omega_S - \omega_I) + J_2(\omega_S + \omega_I)}{\frac{1}{6} J_0(\omega_S - \omega_I) + \frac{1}{2} J_1(\omega_I) + J_2(\omega_S + \omega_I)} \quad (17b)$$

$$R_2 \equiv \frac{1}{NT_2} = \frac{3}{4} \pi^2 \chi_D^2 \left[\frac{1}{6} J_0(\omega_S - \omega_I) + \frac{1}{2} J_1(\omega_I) + J_2(\omega_S + \omega_I) + \frac{2}{3} J_0(0) + J_1(\omega_S) \right] \quad (17c)$$

Here R_{1Z} is the Zeeman (spin-lattice) relaxation rate with relaxation time T_{1Z} ; η_{IS} is the heteronuclear Overhauser effect

due to the fluctuating dipolar interactions; and R_2 is the transverse (spin–spin) relaxation rate with relaxation time T_2 ; N is the number of directly bonded ^1H nuclei. For the case of orientational averaging, the m index vanishes due to the spherical symmetry as mentioned above, such that $J_m(\omega_I) \rightarrow \langle J_m(\omega_I) \rangle \equiv J(\omega_I)$. (See also *Liquid Crystalline Samples: Carbon-13 NMR*.)

4.3 Correlation Functions and Spectral Densities for Restricted Diffusion

Generally speaking, one can employ a simple diffusion model to describe either segmental motions or molecular motions. Let us define generic Euler angles as $\Omega \equiv (\alpha, \beta, \gamma)$; i.e. $\Omega = \Omega_{\text{ID}}$ for segmental diffusion or $\Omega = \Omega_{\text{MD}}$ for molecular diffusion, with generalized projection indices $(m', m) \equiv (r, n)$ or (q, n) . The spectral densities for rotational diffusion $F_{m'm}^{(2)}(\Omega; \omega)$ are Fourier transform partners of the correlation functions $G_{m'm}^{(2)}(\Omega; t)$, as indicated below:

$$F_{m'm}^{(2)}(\Omega; \omega) = \text{Re} \int_{-\infty}^{\infty} G_{m'm}^{(2)}(\Omega; t) e^{-i\omega t} dt \quad (18a)$$

$$\begin{aligned} &\equiv [|\langle D_{m'm}^{(2)}(\Omega) \rangle|^2 - |\langle D_{m'm}^{(2)}(\Omega) \rangle|^2 \delta_{m'0} \delta_{m0}] \\ &j_{m'm}^{(2)}(\Omega; \omega) \end{aligned} \quad (18b)$$

where $G_{m'm}^{(2)}(\Omega; t) = G_{m'm}^{(2)}(\Omega; 0) g_{m'm}^{(2)}(\Omega; t)$. As a rule, $F_{m'm}^{(2)}(\Omega_{\text{ID}}; \omega)$ for segmental diffusion or $F_{m'm}^{(2)}(\Omega_{\text{MD}}; \omega)$ for molecular diffusion are a function of both even and odd rank order parameters.^{16,41} Assuming a value of the second-rank polynomial $\langle D_{00}^{(2)}(\Omega_{\text{ID}}) \rangle$ for segmental motions or $\langle D_{00}^{(2)}(\Omega_{\text{MD}}) \rangle$ for molecular motions, the parameters of the potential of mean torque can be determined.^{39,41}

One can solve the rotational diffusion equation⁴³ in the presence of a uniaxial potential of mean torque to give for the reduced correlation functions

$$\begin{aligned} g_{m'm}^{(2)}(\Omega; t) &= \exp[-(D_{\parallel} - D_{\perp})m'^2 t] \\ &\times \sum_{k=1}^{\infty} c_{m'm}^{(2,k)} \exp(-\alpha_{m'm}^{(2,k)} D_{\perp} t) \end{aligned} \quad (19)$$

Here $\alpha_{m'm}^{(2,k)}$ denotes the k th eigenvalue of the diffusion operator, and $c_{m'm}^{(2,k)}$ and $\tau_{m'm}^{(2,k)}$ are the relative normalized weight and correlation time for the k th relaxation component. (See also *Liquid Crystalline Samples: Relaxation Mechanisms*.) Solutions in closed form are obtained by making a single exponential approximation in terms of a short time expansion,⁴⁴ yielding for the mean of the eigenvalues

$$\alpha_{m'm}^{(2)} = \sum_{k=1}^{\infty} c_{m'm}^{(2,k)} \alpha_{m'm}^{(2,k)} = \frac{\mu_{m'm}}{G_{m'm}^{(2)}(0)} \quad (20)$$

The moments $\mu_{m'm}$ are given by their expansions^{16,44} in terms of the order parameters $\langle D_{00}^{(j)}(\Omega) \rangle$. Within the single

exponential approximation, the correlation times are denoted by

$$\frac{1}{\tau_{m'm}^{(2)}} = [\alpha_{m'm}^{(2)} + (\eta_{\text{diff}} - 1)m'^2] D_{\perp} \quad (21)$$

where $\eta_{\text{diff}} \equiv D_{\parallel}/D_{\perp}$ and $\mathbf{D}$ is the rotational diffusion tensor. The reduced correlation functions are then given by

$$g_{m'm}^{(2)}(\Omega; t) = \exp(-t/\tau_{m'm}^{(2)}) \quad (22)$$

and likewise the reduced spectral densities are given by

$$j_{m'm}^{(2)}(\Omega; \omega) = \frac{2\tau_{m'm}^{(2)}}{1 + (\omega\tau_{m'm}^{(2)})^2} \quad (23)$$

4.4 Segmental Motions

In the case of segmental motions the dynamics can involve dihedral angle isomerizations together with torsional oscillations. For simplicity and generality, one can assume a diffusion model³⁹ in terms of the angles $\Omega_{\text{PD}}(t)$ between the frame of the coupling tensor and the director; alternatively, jump models can be considered.^{45–47} The result for the irreducible spectral densities $J_m(\omega)$ in the laboratory frame can be expressed in general as^{41,48,49}

$$\begin{aligned} J_m(\omega) &= \sum_r \sum_n |D_{0r}^{(2)}(\Omega_{\text{PI}}) - \sqrt{\frac{1}{6}} \eta_{\lambda} [D_{-2r}^{(2)}(\Omega_{\text{PI}}) \\ &+ D_{2r}^{(2)}(\Omega_{\text{PI}})]|^2 F_{rn}^{(2)}(\Omega_{\text{ID}}; \omega) |D_{nm}^{(2)}(\Omega_{\text{DL}})|^2 \end{aligned} \quad (24)$$

For either the dipolar or quadrupolar interactions, the asymmetry parameter, η_{λ} , describes the deviation of the static coupling tensor from cylindrical symmetry, as noted above. The squares of the Wigner rotation matrix elements $|D_{m'm}^{(2)}(\Omega)|^2$ are given in terms of their Clebsch–Gordan series expansions.¹⁵ Note that in general the orientation dependence of the relaxation is described by the factor $|D_{nm}^{(2)}(\Omega_{\text{DL}})|^2$.

4.5 Molecular Motions

Likewise, one can apply a diffusion model to restricted molecular rotations within the potential of mean torque of the bilayer. Here the molecular motions are formulated in terms of reorientation of a single molecule in the mean field due to all its neighbors. The slow motions may be noncollective, i.e. ‘molecular’ in nature, and involve wobbling or rattling of the lipid as described by the angles $\Omega_{\text{MD}}(t)$ between the molecular frame and the director. It is simple to show³⁹ that the relaxation rates are isomorphous to those for segmental motions,³⁸ in which $\chi_{\lambda} \rightarrow \chi_{\lambda}^{\text{eff}}$ and $\eta_{\lambda} \rightarrow \eta_{\lambda}^{\text{eff}}$. The spectral densities are scaled by the local order parameter squared, which gives

$$\begin{aligned} J_m(\omega) &= |\langle D_{00}^{(2)}(\Omega_{\text{PI}}) \rangle|^2 \sum_q \sum_n |D_{0q}^{(2)}(\Omega_{\text{IM}}) \\ &- \sqrt{\frac{1}{6}} \eta_{\lambda}^{\text{eff}} [D_{-2q}^{(2)}(\Omega_{\text{IM}}) + D_{2q}^{(2)}(\Omega_{\text{IM}})]|^2 \\ &\times F_{qn}^{(2)}(\Omega_{\text{MD}}; \omega) |D_{nm}^{(2)}(\Omega_{\text{DL}})|^2 \end{aligned} \quad (25)$$

Here the two coupling parameters are $\chi_\lambda^{\text{eff}} = \chi_\lambda \langle D_{00}^{(2)}(\Omega_{\text{PI}}) \rangle$ and $\eta_\lambda^{\text{eff}} = -\frac{3}{2} \langle \sin^2 \beta_{\text{PI}} \cos(2\gamma_{\text{PI}}) \rangle / \langle D_{00}^{(2)}(\Omega_{\text{PI}}) \rangle$. Because the spectral densities are multiplied by $|\langle D_{00}^{(2)}(\Omega_{\text{PI}}) \rangle|^2$, the local order parameter squared, the static coupling constant $\chi_\lambda^2 \rightarrow (\chi_\lambda^{\text{eff}})^2$ in the relaxation rate expressions, equations (15)–(17). Now if the orientations of the residual tensor principal axes, together with the mean-squared amplitudes and reduced spectral densities of the slow motions as described by $F_{\text{qn}}^{(2)}(\Omega_{\text{MD}}; \omega)$, are nearly constant, then the dependence of the relaxation on chain position is largely governed by the two quantities $\chi_\lambda^{\text{eff}}$ and $\eta_\lambda^{\text{eff}}$. Assuming the effective asymmetry parameter $\eta_\lambda^{\text{eff}}$ is nearly zero or constant along the chain, then a square law functional dependence of the spectral densities on the observed segmental order parameter S_{CD} results.^{18,39,50}

4.6 Collective Motions

As an alternative to considering distinct rotational modes, one can adopt a three-dimensional picture for the bilayer in terms of a continuum of twist, splay, and bend deformations as proposed by Brown.³⁹ It is assumed that the various chain segments reorient collectively, in which the key distinction from the above molecular picture is that a broad distribution of wave-like elastic modes is present.^{39,51,52} Here the shorter wavelengths approach the molecular or chain diameter, where of course the continuum description breaks down; the longer wavelengths approach the macroscopic dimensions of the bilayer and for simplicity are taken as ∞ . The slow motions are described by the angles $\Omega_{\text{ND}}(t)$ between the instantaneous (or local) director and the average director (the bilayer normal), where a small angle approximation is made.

For such a picture one obtains that

$$J_m(\omega) = C |\langle D_{00}^{(2)}(\Omega_{\text{PI}}) \rangle|^2 |\omega|^{-1/2} |D_{\pm 1m}^{(2)}(\Omega_{\text{DL}})|^2 \quad (26)$$

in which C is a collection of various constants (a single elastic constant approximation is made). The angular anisotropy is described by the factor $|D_{\pm 1m}^{(2)}(\Omega_{\text{DL}})|^2$ and thus reflects the assumption of small angle director fluctuations. Assuming that the amplitude of the slow motions is nearly uniform along the chain, a squared dependence on the observed order parameter results as for the molecular model (vide supra). Alternatively, a two-dimensional picture in terms of fluctuations of the lipid/water interface can be considered, in which the finite thickness of the bilayer is disregarded.⁵³ Such a formulation is analogous to a smectic undulation model, in which there is a large increase in the elastic constants for the twist and bend modes.⁵⁴ Hence only splay is considered in terms of a single elastic constant K_c ; this yields

$$J_m(\omega) = C' |\langle D_{00}^{(2)}(\Omega_{\text{PI}}) \rangle|^2 |\omega|^{-1} |D_{\pm 1m}^{(2)}(\Omega_{\text{DL}})|^2 \quad (27)$$

where C' is similarly a collection of elastic and other constants.

4.7 Observed Spectral Densities

Now the presence of a motional hierarchy means that the residual interaction due to an individual component is further modulated by the slower motions of larger orientational amplitude. Let us modify our notation and denote the observed order parameter by $S^{(2)} \equiv S_{\text{CD}}$. The following product approximation can be made if the fast and slow motions are axially symmetric:⁵⁵

$$S^{(2)} = S_f^{(2)} S_s^{(2)} \quad (28)$$

One can then write for the spectral densities that

$$J_m(\omega) = J_m^f(\omega) + J_m^s(\omega) \quad (29)$$

where, in principle, both the fast and slow contributions depend on the (i) degree of ordering, (ii) frequency, and (iii) orientation.^{39,40}

Further simplification is possible if one assumes that orientational averaging of the relaxation occurs, e.g. as in the case of vesicles and also multilamellar dispersions.⁵⁶ We shall denote $S_f^{(2)} \equiv \langle D_{00}^{(2)}(\Omega_{\text{PI}}) \rangle$ as the order parameter for the fast motions, and $S_s^{(2)} \equiv \langle D_{00}^{(2)}(\Omega_{\text{ID}}) \rangle$ as the order parameter for the slow motions. The spectral density for the fast motions is given by³⁹

$$J_f^f(\omega) = \frac{1}{5} [1 - S_f^{(2)2}] j_f^{(2)}(\omega) \quad (30)$$

in which

$$j_f^{(2)}(\omega) = \frac{2\tau_f^{(2)}}{1 + [\omega\tau_f^{(2)}]^2} \quad (31)$$

Here $\tau_f^{(2)}$ is the correlation time for the motions with respect to the local director axis (internal frame).

In the case of the spectral densities due to slow motions, a molecular model can be considered, or alternatively a collective model; the spectral densities are scaled by the fast order parameter squared, viz. $S_f^{(2)2}$. Assuming a single correlation time, one obtains for the orientationally averaged spectral density that³⁹

$$J_s^s(\omega) = \frac{1}{5} S_f^{(2)2} [1 - S_s^{(2)2}] j_s^{(2)}(\omega) \quad (32)$$

where

$$j_s^{(2)}(\omega) = \frac{2\tau_s^{(2)}}{1 + [\omega\tau_s^{(2)}]^2} \quad (33)$$

Note that if the correlation time for the slow motions is sufficiently long so that $[\omega\tau_s^{(2)}]^2 \gg 1$, then a ω^{-2} frequency dependence results.⁵⁵ However, in general the frequency dependence is more complicated.³⁹

It is worth noting that if the slow motion is unrestricted, e.g. as occurs in globular proteins⁵⁶ or detergent micelles,⁵⁷ then there is no preferred symmetry axis (corresponding to the

average director) and hence the slow order parameter $S_s^{(2)} \rightarrow 0$; this gives

$$J^s(\omega) \rightarrow \frac{1}{5} S_f^{(2)2} j_s^{(2)}(\omega) \quad (34)$$

One then immediately obtains as a limiting case the results formulated independently by Lipari and Szabo⁵⁶ as the ‘model-free approach’, or by Wennerström and co-workers⁵⁷ as the ‘two-step model’. (See also *Protein Dynamics from NMR Relaxation* and *Micellar Solutions and Microemulsions*.) Because the present treatment^{38–40} is more general, it is referred to as the ‘generalized approach’.¹²

For the collective model, the orientationally averaged spectral density due to the slow motions is given by

$$J^s(\omega) = \frac{1}{5} S_f^{(2)2} j_s^{(2)}(\omega) \quad (35)$$

where

$$j_s^{(2)}(\omega) = C \omega^{-1/2} \quad (36)$$

Here C is a collection of elastic and other constants; a single elastic constant approximation is made for the twist, splay, and bend modes. Alternatively, a two-dimensional smectic-like formulation can be considered.^{53,54} Such a treatment in terms of splay only gives^{53,54}

$$j_s^{(2)}(\omega) = C' \omega^{-1} \quad (37)$$

where C' is similarly a collection of elastic and other constants.

5 TESTING OF CONCEPTUAL FRAMEWORKS

As indicated above, the spectral densities $J_m(\omega)$ and associated relaxation rates depend on the segmental ordering, frequency ω (magnetic field strength), temperature, and the bilayer orientation.³⁹ For the sake of illustration, let us again consider the order and relaxation profiles depicted in Figure 4.¹⁶ One plausible interpretation is that the static interaction constant is modulated by the motions; here the residual or effective quadrupolar coupling (≈ 30 – 40 kHz) is smaller than the static quadrupolar coupling (170 kHz), so that the mean

Figure 6 Plots of $^2\text{H } R_{\text{IZ}}^{(i)}$ rates versus the corresponding values of $|S_{\text{CD}}^{(i)}|^2$ for acyl segments of DLPC- d_{46} in the liquid crystalline phase at 46.1 MHz and 40 °C. (a)–(d) Results for bilayers aligned on planar substrates at different angles (θ) with respect to the main magnetic field. (Reproduced by permission of the American Institute of Physics from T. P. Touard, T. M. Alam, and M. F. Brown, *J. Chem. Phys.*, 1994, **101**, 5229)

squared amplitudes provide a relatively minor influence. As a result the relaxation profile is governed by the local motional rates along the chain. Another possibility is that the interaction varies along the chain, and corresponds not to the static coupling, but rather to an effective or residual coupling that is preaveraged by faster motions of a more local nature, e.g. dihedral angle isomerizations.⁴⁸ Instead of the static coupling being constant and the dynamical parameters varying along the chain, the opposite holds. The coupling parameters as reflected in the mean-squared amplitudes vary with the chain position, and thus govern the shape and magnitude of the relaxation profile, whereas the dynamical parameters are essentially the same. What is the correspondence to equilibrium and dynamical properties of bilayers in the fluid phase?

To interpret further such relaxation profiles, it is necessary to introduce motional models which encompass the key physics of interest. As already noted, the angular anisotropy of the relaxation for $I = 1$ nuclei is related to the orientation and symmetry of the coupling tensor within the frame undergoing the fluctuations, i.e. the segment, molecule, or bilayer.³⁹ Fits of the angular dependence of the R_{1Z} rates of lipid bilayers in the fluid (L_α) phase to the segmental, molecular, and collective models can all explain the angular dependence for disaturated phosphatidylcholines to a greater or lesser degree of success, depending on the number of adjustable parameters.¹⁶ How can one further distinguish among these different interpretations?

In this regard, the magnitude of the ^2H and ^{13}C relaxation times together with their dependence on frequency and temperature renders it unlikely that an interpretation in

Figure 7 Plots of natural-abundance ^{13}C spin-lattice relaxation rates, $R_{1Z}^{(i)}$, for acyl chain segments of DPPC vesicles versus $|S_{\text{CD}}^{(i)}|^2$ from ^2H NMR studies at various temperatures in the liquid crystalline state. (a)–(g) Results obtained at different ^{13}C frequencies (magnetic field strengths). (Reproduced by permission of the American Institute of Physics from M. F. Brown, *J. Chem. Phys.*, 1984, **80**, 2808)

terms of a single type of local motion can explain the results.^{39,40} Such a formulation has been suggested as a first approximation for describing the dynamics in fluid L_α phase bilayers.^{35,38} However, subsequent studies have indicated that a fundamentally different physical picture may be involved.^{18,19,39} As a result, the possible influences of slow motions which modulate the residual coupling left over from faster local motions must be considered. Figure 6 shows that if the ^2H $R_{1Z}^{(i)}$ rates are plotted versus the corresponding values of the order parameters, $S_{CD}^{(i)}$, squared, a nearly straight line results. The presence of such a square law dependence was first recognized by Brown,³⁹ and represents a hallmark or characteristic signature of the fluid, liquid crystalline state of disaturated lipid bilayers. The experimentally observed square law functional dependence of $R_{1Z}^{(i)}$ and $S_{CD}^{(i)}$ is independent of any motional model. It can be readily explained by Fermi's Golden Rule, in which the strength of the interaction depends on the matrix elements squared, and thus varies with the chain position; the motional parameters are largely constant. Consequently, although the slow motions provide the dominant contribution to the observed relaxation rates, the internal fast motions govern the relaxation profile along the chains.

Further information can be obtained from ^{13}C NMR studies, in which the relaxation is due to the direct magnetic dipolar interaction of the ^{13}C nucleus with the directly bonded ^1H atoms. By carrying out ^{13}C NMR R_{1Z} studies of small vesicles, it is possible to employ conventional high-resolution NMR spectrometers to obtain relaxation data at different magnetic field strengths. As noted above, ^{13}C R_{1Z} studies of both small vesicles of phosphatidylcholines as well as the corresponding multilamellar dispersions evince little difference in their relaxation rates.^{18,20} Hence the motions governing the relaxation in the megahertz regime in both cases must be rather similar. In Figure 7 the natural-abundance ^{13}C NMR R_{1Z} relaxation rates of DPPC small vesicles obtained at seven magnetic field strengths,¹⁸ covering a range of ^{13}C frequencies from 15.0 MHz (1.40 T) to 126 MHz (11.7 T), are plotted versus the square of the corresponding ^2H NMR order parameters, S_{CD} . As in the case of the ^2H NMR data, evidence of a square law relation is found, as discussed above. Moreover, a comparison of the data in Figure 7(a)–(g) reveals a progressive decrease in the slopes of the square law plots as the ^{13}C frequency is increased from 15.0 to 126 MHz, i.e. there is a characteristic frequency dependence of the relaxation in agreement with earlier ^1H NMR studies.¹⁷

At present, the most extensive frequency-dependent R_{1Z} relaxation data for lipid vesicles comprise ^2H NMR studies of specifically deuterated 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC). The results encompass nine different magnetic field strengths, ranging from 2.5 MHz (0.38 T) to 62.4 MHz (9.55 T), employing both electromagnets and superconducting NMR magnets.¹⁹ Figure 8 summarizes the results of fitting the dispersion data for DMPC deuterated at the C-3 position to (i) the three-dimensional collective model involving twist, splay, and bend deformations, (ii) the two-dimensional interfacial collective model involving splay only, and, finally, (iii) the noncollective molecular model formulated in terms of a single Lorentzian plus a constant to account for internal motions. It is noteworthy that vesicle tumbling is too slow to influence appreciably the relaxation in the megahertz regime.¹⁹ As can be seen, the $\omega_I^{-1/2}$ dependence^{39,58} provides the best fit to the data; fits to an ω_I^{-1} dependence in terms of splay

Figure 8 Deuteron R_{1Z} rates as a function of frequency for vesicles of DMPC deuterated at the C-3 acyl segment at 30 °C in the liquid crystalline state. Data are indicated at nine different frequencies (magnetic field strengths) and are fitted to the various relaxation laws described in the text. (Reproduced by permission of Taylor and Francis Ltd. from M. F. Brown, A. Salmon, U. Henriksson, and O. Söderman, *Mol. Phys.*, 1990, **69**, 379)

only⁵³ or to a Lorentzian dispersion⁵⁵ are clearly not as successful. One should also note that a different interpretation of these preliminary R_{1Z} relaxation rate data has appeared.⁵⁹

With regard to the various acyl chain positions, the ^{13}C NMR measurements for DPPC at the seven different magnetic field strengths are currently the most extensive data available.¹⁸ The ^{13}C R_{1Z} rates can be plotted as a function of $\omega_C^{-1/2}$ in accord with the three-dimensional collective model; the slopes are seen in Figure 9 to decrease progressively along the chain. This is to be expected since the relaxation rates depend on the order parameter S_{CH} ($=S_{CD}$) squared. Additional information is obtained from ^{13}C – ^1H heteronuclear Overhauser effect (NOE) studies of vesicles of disaturated phosphatidylcholines. The predicted NOE = $1 + \eta_{IS}$ of 2.34 for the collective model⁴⁰ is in good agreement with experimental data, which reveal little dependence on the magnetic field strength.⁶⁰

Figure 9 Plots of natural-abundance ^{13}C spin-lattice relaxation rates, R_{1Z} , for acyl chain segments of DPPC vesicles versus $\omega_C^{-1/2}$ at 50°C in the liquid crystalline state.⁴⁰ Data are indicated at seven ^{13}C frequencies (magnetic field strengths) and are fitted to a collective relaxation law. The inset shows the contribution from fast local motions plotted against the spin-lattice relaxation rates of the corresponding segments of *n*-hexadecane, where the dashed line indicates a slope of $m = 1$. (Reproduced by permission of the American Institute of Physics from M. F. Brown, *J. Chem. Phys.*, 1984, **80**, 2808)

In fact, the entire body of ^2H R_{1Z} data for multilamellar dispersions and ^{13}C R_{1Z} data for vesicles of disaturated phosphatidylcholines are consistent with a relaxation law in which the spectral densities due to slow motions have the form of equation (35) and (36). Moreover, by subtracting the local contribution and normalizing the various R_{1Z} data by the square of the ^2H NMR order parameters, one can superimpose all of the data for all of the nuclei, viz. including ^1H , ^2H , and ^{13}C on a common plot versus $\omega_I^{-1/2}$ as indicated in Figure 10(a). Here it is necessary to assume¹² a vibrationally averaged ^{13}C - ^1H dipolar coupling constant corresponding to $\langle r_{\text{CH}}^{-3} \rangle^{-1/3} = 0.114\text{nm}$ rather than the equilibrium bond length $r_{\text{CH}} = 0.109\text{nm}$ as in Figure 10(b). This is in agreement with independent estimates of the ^{13}C - ^1H dipolar coupling constant and the ^{13}C - ^2H quadrupolar coupling constant.¹³

6 EQUILIBRIUM AND DYNAMICAL PROPERTIES OF LIPID BILAYERS

A summary of the currently available NMR results for multilamellar dispersions and small vesicles of DPPC is provided in Figure 11.^{18,39} The square law functional dependence of the ^2H R_{1Z} relaxation rates and ^2H NMR order parameters is illustrated in the case of DPPC multilamellar dispersions in Figure 11(a); in addition, the $\omega_C^{-1/2}$ frequency dispersion found in ^{13}C R_{1Z} relaxation studies of small DPPC vesicles is displayed in Figure 11(b). Both dependencies are characteristic signatures of the fluid L_α phase of membrane lipid bilayers.³⁹ By contrast, Figure 11(b) shows that the ^{13}C R_{1Z} rates of liquid alkanes such as *n*-hexadecane are essentially independent of frequency, i.e. magnetic field strength, over the range investigated.¹⁸

The presence of a hierarchy of motions in lipid bilayers was first recognized by the Chan¹⁷ and Klein⁵ groups, and

Figure 10 Plots of normalized contribution from slow motions to ^1H , ^2H , and ^{13}C R_{1Z} rates versus $\omega_I^{-1/2}$ for various acyl chain segments of DPPC at 50°C in the liquid crystalline state ($\omega_0 \equiv \omega_I$). In (a) a vibrational averaged ^{13}C - ^1H distance ($r_{\text{CH}}^{(0)} \equiv \langle r_{\text{CH}}^{-3} \rangle^{-1/3}$) of 0.114 nm is used; whereas in (b) the equilibrium bond length of 0.109 nm is assumed. (Reproduced by permission of the American Institute of Physics from M. F. Brown, *J. Chem. Phys.*, 1984, **80**, 2832)

subsequently interpreted in terms of collective dynamics by Brown.³⁹ (See also *Slow and Ultraslow Motions in Biology*.) One can model the proposed bilayer order fluctuations in terms of twist, splay, and bend deformations in the high-frequency or free membrane limit, and possibly by smectic undulation modes involving splay only in the low-frequency or strongly coupled limit.¹⁸ Figure 12 shows a schematic illustration from a 1979 conference at Stanford University, which indicates the types of collective excitations that can explain the frequency- and ordering-dependent relaxation enhancement of membrane bilayers.¹⁸ For such a continuum picture, the higher-frequency modes have smaller amplitudes, whereas the lower-frequency modes have larger amplitudes; the high- and low-frequency cutoffs are neglected for simplicity. Following Blinc et al.,⁵⁴ there are two limits for a smectic A mesophase such as a bilayer dispersion, depending on the repeat distance d between the layers relative to the wavelength λ . First there is the high-frequency regime where $\lambda \ll d$, corresponding to the free membrane limit where coupling between the bilayers is negligible; in this case the relaxation is similar to the nematic phase. Secondly, there is the low-frequency regime

Figure 11 Summary of NMR results for DPPC at 50°C in the liquid crystalline state. (a) Plot of ^2H spin-lattice relaxation rates $R_{1Z}^{(i)}$ versus $|S_{\text{CD}}^{(i)}|^2$ for acyl segments of multilamellar dispersions; (b) plot of ^{13}C spin-lattice relaxation rates, R_{1Z} , for $(\text{CH}_2)_n$ resonance versus $\omega_C^{-1/2}$ for small vesicles

where $\lambda \gg d$. In this case there is the possibility of smectic undulation waves having a constant interlamellar distance,^{53,54} in which the restriction to splay only leads to an ω^{-1} frequency dependence over the entire range; other modes are possible.

Thus at higher frequencies in the megahertz regime, within the free membrane limit, a nematic-like behavior is found comprising relatively short-wavelength twist, splay, and bend modes, yielding the experimentally observed $\omega^{-1/2}$ dependence.^{39,51,54,61} On such a length scale, no direct correspondence exists between the microscopic elastic constants and the bulk elastic constants that are experimentally measured. Because the R_{1Z} rates for vesicles and multilamellar dispersions are nearly the same,³⁵ the megahertz dispersion most likely does not arise from two-dimensional surface fluctuations.⁵³ However, at lower frequencies in the kilohertz regime, the properties of the membrane lipid/water interface become increasingly important, and a transition occurs to the strongly coupled limit involving interactions among the different layers. There may now be a correspondence with the bulk elastic constant as experimentally measured; additional research is necessary. The restriction to splay only for the lower-frequency modes leads to an ω^{-1} frequency dependence in the kilohertz regime.⁵⁴ (See also *Molecular Motions: T_1 Frequency Dispersion in Biological Systems*.)

Figure 12 Examples of the types of collective bilayer excitations leading to $\omega^{-1/2}$ frequency dependence. (a) Twist. (b) Splay

Finally, the contribution from local internal motions is obtained by extrapolating the ordering- and frequency-dependent relaxation enhancement for a fluid lipid bilayer to zero ordering or infinite frequency (see Figure 11). As a result, one can conclude that the microviscosity of the bilayer hydrocarbon region, where a bulk viscosity cannot be measured, is essentially equivalent to liquid *n*-alkanes having a macroscopic viscosity on the order of a few centipoise! It follows that the membrane lipid/water interface may be very important with regard to lateral diffusion of membrane lipids and proteins. These previous conclusions^{18,39} are now supported by detailed molecular mechanics studies of membrane bilayers in the fluid phase.^{62,63} With the advent of more powerful computers, one can expect the availability of longer timescales, so that the motional distribution proposed on the basis of NMR spectroscopy can be further addressed.

1 INTRODUCTION

Because they constitute the basic structural component of biological membranes, bilayers composed of fatty acid containing amphiphiles have been the object of extensive study by NMR over the last three decades. The bulk of this work has been performed on fatty acid soaps and phosphatidyl glycerol esters of fatty acids phospholipids. Depending on water content and temperature, these substances exist in a number of well-characterized phases. The two phases of primary importance as biological membrane models are the smectic gel and liquid crystalline phases, between which there is a first-order melting transition. In both phases, the amphiphile molecules are organized as extended bilayers, separated by hydration regions in contact with the polar head groups of the amphiphile molecules. These are called multilamellar liposomes (in the case of lipids) or lyotropic liquid crystals (typically for soaps). In addition, closed single spherical bilayer structures are also possible for most lipids, termed unilamellar vesicles. These are normally generated by high-frequency agitation (ultrasonic irradiation) of lipid/water dispersions. They represent only a quasistable thermodynamic state when small (less than ~20 nm radius). A detailed description of bilayer systems is given in Chapman and Salsbury.¹

The first NMR studies on bilayers were performed by Lawson and Flautt,² who examined aqueous dispersions of fatty acid soaps. Chapman and coworkers³ soon after performed the first NMR studies on phospholipid bilayer dispersions. These, and almost all of the other early investigations by Chan and colleagues (see, for example, Bocian and Chan⁴ for a review) involved ¹H NMR, although the studies by Chapman et al. pioneered the use of selective deuteration to isolate contributions to the total lipid ¹H spectrum of different proton components of the lipid molecule.

After the proton, the ¹⁹F nucleus has the next highest NMR sensitivity of any stable isotope (~83% of the sensitivity of ¹H) and like ¹H, has essentially 100% natural abundance. In addition, due to its inertness and small size, a fluorine atom may often replace a proton, in say a C–H bond, with minimal disturbance to the biological properties and structure of the recipient molecule. Since fluorine is not normally present

in biological systems, and bilayer-forming amphiphiles in particular, this offers the great potential advantage of being able to label specific portions of a molecule for study by NMR. Moreover, ¹⁹F has a much higher range of chemical shifts than ¹H, and as such the ¹⁹F shift is much more responsive to environmental perturbations than the ¹H shift. This allows the ¹⁹F nucleus to be a very sensitive reporter of both molecular environment and motional state. There is, however, the caveat that the atom is larger, and the bond to carbon longer than the corresponding case for hydrogen. Thus ¹⁹F cannot be a totally ‘nonperturbing’ probe of the molecular proton environment in the way that deuterium, (²H) is. However, deuterium has only ~1% of the NMR sensitivity of ¹H or ¹⁹F and its NMR spectroscopy is somewhat more technically demanding than is that for the latter nuclei. These factors combine to make ¹⁹F labeling a useful NMR tool in many instances. The balance of data at present (see below) appears to suggest that ¹⁹F is a good qualitative reporter of the C–H proton environment in bilayer systems, but that there are modest quantitative differences between motional behavior of C–F and the corresponding C–H groups.

To minimize disturbance and exploit the capacity for precise label localization, essentially all ¹⁹F NMR studies on bilayers have been performed on systems composed of selectively fluorinated molecules. Most commonly these have involved phospholipids, singly or doubly ¹⁹F substituted at the same methylene carbon in the acyl chain region. Two groups have been prominent in this work, those of Ho (see, for example Ho et al.⁵) and McElhaney (see *Membrane Lipids of Acholeplasma laidlawii*). When allowance is made for the moderate perturbations alluded to above, the results of these and other workers show that ¹⁹F labeling provides an uniquely useful ‘window’ into the structural and dynamic states within bilayer membranes. The ¹⁹F nucleus shares with ¹H its NMR sensitivity and capacity for significant internuclear dipolar interaction (see below), while possessing the strong ‘bond centered’ orientational properties of quadrupolar ²H spectroscopy, due to the typically large chemical shift anisotropy of ¹⁹F.

NMR is able to probe a wide range of molecular motional timescales through the frequency dependence of magnetization relaxation rates. Such studies have been arguably the most important and revealing applications of ¹H and ¹⁹F NMR to bilayer systems. With current techniques, molecular motions with characteristic times in the range ~10⁻⁵–10⁻¹¹ s may be examined. The pioneering studies in this area on bilayer systems were performed by Chan and coworkers (see, for example, Feigenson and Chan⁶), who were the first to establish that a range of molecular motional timescales existed within bilayers and that the broad proton resonances seen from such systems arose from incomplete orientational averaging within an anisotropic environment (see below). This gave the first direct indication that even in the ‘fluid’ L_α liquid crystalline phase, the hydrocarbon interior of the bilayer was still partially ordered. An important subsequent development of this approach, certainly for ¹H and ¹⁹F NMR studies, was the use of macroscopically aligned hydrated bilayer samples and wide-line, solid state NMR techniques to study both the frequency and angular (relative to the external field) dependences of relaxation parameters. The main contributions in these areas have come over the last decade from Cornell

and colleagues (see, for example, Pope et al.⁷) for ^1H and Ho et al.⁸ for ^{19}F labeled systems.

Precisely because of the incomplete motional averaging which occurs in bilayers, the ^1H spectra of bilayer dispersions tend to be broad and relatively featureless. Small unilamellar vesicles (which tumble rapidly in solution) give moderately well-resolved ^1H spectra, and allow ‘high-resolution’, two-dimensional techniques (such as NOESY ^1H – ^1H Overhauser spectroscopy) to be employed (see, for example, Ellena et al.⁹). This is particularly useful for the headgroup region resonances (e.g. the choline methyl groups in phospholipids). However, recently it has been demonstrated by Forbes et al.¹⁰ that magic angle sample spinning techniques, which largely average out the ^1H – ^1H dipolar interactions, give well-resolved ^1H spectra from the liquid crystalline mesophase of soap or lipid dispersions. While gel phase systems, which possess much less internal motion than L_α phase samples, still present difficulties for the technique, it is clear that this approach will find increasing applications in the future for the NMR study of bilayers (see, for example Lee and Griffin¹¹).

2 DIPOLAR AND CHEMICAL SHIFT INTERACTIONS

Both ^1H and ^{19}F have nuclear spin, $I = \frac{1}{2}$ (no quadrupolar effects), large values of the nuclear gyromagnetic ratio γ , and relatively small atomic excluded volume radii. The latter means that internuclear separations at van der Waals contact are only $\sim 0.2\text{ nm}$ for these atoms in systems of interest here. These factors combine to ensure that after the Zeeman interaction, orientation-dependent *nonbonded* internuclear dipolar interactions are major contributors to the ^1H and ^{19}F spin Hamiltonian in systems such as bilayers, which lack complete motional averaging on the relevant NMR timescale. In addition, the Zeeman coupling to the external field has itself an orientation dependence, due to the variation in chemical shift screening with direction in a molecule fixed coordinate frame. For protons in C–H groups this variation is negligible ($< 1\text{ ppm}$) and will be ignored here, but for ^{19}F in C–F groups it is substantial ($\sim 200\text{ ppm}$) and may dominate the spectrum. Both the dipolar and chemical shift interaction energies may be written in compact form using irreducible tensor formalism.^{12,13} This has the virtue of emphasizing the common orientational dependence features of these basically quite different physical effects. Moreover, we will be concerned mainly with the pure ‘orientation-only’ component of these interactions, i.e. those that average to zero over the sphere. For the dipole–dipole term this is the total interaction itself, and for the chemical shift term it is the total interaction minus the isotropic shift, which difference we call the chemical shift anisotropy (CSA). Then either the $\hat{\mathcal{H}}_{\text{D}}$ or $\hat{\mathcal{H}}_{\text{CSA}}$ interaction Hamiltonians may be written:

$$\hat{\mathcal{H}}(t) = \sum_{q=-2}^2 F_q(t) \hat{T}_q \quad (1)$$

For dipolar interactions the $F_q(t)$ are proportional to the spherical harmonics of order 2:¹²

$$F_q[\Omega(t)] \simeq [1/r(t)^3] Y_{2,q}[\Omega(t)] \quad (2)$$

where the internuclear separation, r , and its polar orientation, Ω , in the laboratory frame may both be functions of time. For the CSA interaction, the $F_q(t)$ are proportional to the components of the irreducible CSA tensor in the laboratory frame. The $\hat{T}_q$ are second-rank-tensor operators, formed from the relevant spin/magnetic field operators in each case (see Wennerström and Lindblom¹⁷ for details). The utility of equations (1) and (2) is that, irrespective of their physical nature, the F_q terms have the same transformation properties under axis rotations and all of the orientation dependence of the interactions is contained in these terms.

At all normal experimental field strengths used in NMR, the Zeeman interaction totally dominates all other terms in the Hamiltonian, that is the nuclear spins are quantized along the external magnetic field at equilibrium. This means that the basic NMR spectrum shape is determined by the ‘static’ (motionally averaged) component of the dipolar or CSA interaction terms, and that only such effects contributing in first-order perturbation theory need be considered (i.e. only the spin components parallel to the external field contribute). The time-dependent parts of the interactions determine relaxation behavior, in a manner reflecting the amplitudes and timescales of molecular motions in the system.¹³ Both the static and dynamic elements of ^1H and ^{19}F NMR have proved extremely valuable in ‘decomposing’ the molecular motions within partially ordered media, such as bilayers, and have allowed direct study of processes with timescales ranging from $\sim 10^{-6}$ – 10^{-11} s .

3 SPECTRAL SHAPES—MULTILAMELLAR DISPERSIONS

For simple ^1H NMR on bilayers, the spectral shape is governed by the only component, $\hat{\mathcal{H}}_{\text{stat}}$, of equation (1) which contributes in first order. This derives from the $q = 0$ term. For any given proton, proton pair (labeled 1,2)

$$\hat{\mathcal{H}}_{\text{stat}} = a \hat{I}_{z1} \hat{I}_{z2} \cdot \frac{1}{2} [(3 \cos^2 \beta_{1,2} - 1)/r_{1,2}^3] ; a = \hbar^2 \gamma_{\text{H}}^2 \quad (3)$$

where $\hat{I}_z$ is the nuclear spin component along the external field axis (z axis), $\beta_{1,2}$ is the angle between the internuclear vector and the external field, and $\hbar = h/2\pi$ where h is Planck’s constant. The bar indicates averaging over all motions faster than the timescale set by the inverse of the typical dipole–dipole interaction (in frequency units). This latter interaction is $\sim 60\text{ kHz}$ for a pair of geminal CH_2 protons (see below).

Two distinct types of averaging are contained in equation (3), that over β and that over r . In the high temperature, fluid liquid crystalline (L_α) phase of bilayers, rapid molecular reorientation, and lateral diffusion average the r dependence of the intermolecular dipolar contribution to zero on a timescale of $\sim 10^{-8}\text{ s}$ (see, for example, Pace and Chan,¹⁴ and below). In the hexagonal intermediate ($\text{P}_{\beta'}$) and low-temperature orthorhombic ($\text{L}_{\beta'}$) phases, the hydrocarbon chains are mainly in a rigid, all-*trans* configuration, with highly restricted lateral mobility. However, relatively free rotational motion occurs about the long chain axis, especially in the $\text{P}_{\beta'}$ phase,¹⁵ and the r^{-3} dependence then ensures that this axially symmetric

Figure 1 (a) All-*trans*-methylene chain showing the most important dipolar interactions and ^{19}F chemical shift tensor orientation which project onto the chain axis during fast axial rotation. (b) Comparison of an experimental (left) and theoretical (right) proton NMR spectrum (100 MHz) for the L_{α} phase of a DMPC/water dispersion as described in the text. [Data of Ulmuis et al. (in Wennerström and Lindblom¹⁷)]

motion largely eliminates intermolecular contributions to equation (3), even in the absence of lateral diffusion. Thus the proton NMR spectrum shape is dominated by purely intramolecular dipolar interactions, both above and below the main ($P_{\beta'} \leftrightarrow L_{\alpha}$) phase transition.

Seiter and Chan¹⁶ showed that under such conditions of fast axial molecular averaging, the effective intramolecular dipolar interactions were ‘projected’ onto the local axis about which the total motion was symmetric. Under these circumstances (see also Section 5)

$$\frac{1}{2} \frac{\overline{(3 \cos^2 \beta_{1,2} - 1)/r_{1,2}^3}}{1} = \frac{1}{2} \frac{\overline{(3 \cos^2 \beta'_b - 1)/r_b^3}}{1} \cdot \frac{1}{2} \times (3 \cos^2 \beta' - 1) \quad (4)$$

where the subscript b refers to the local molecular coordinate system and β' now refers to the orientation of the local averaging axis to the main field direction. For an all-*trans* chain rotating about the chain axis, the principal projected interactions for a given proton are shown in Figure 1(a). The strongest of these is the methylene geminal pair interaction, which is the only one for which r'_b is constant (0.182 nm) in all chain geometries. The 22 kHz β methylene interactions are substantially reduced for configurations other than all-*trans*, due to β'_b being then closer on average to the magic angle (54.7°), and r'_b being larger on average than 0.25 nm.

Figure 1(b) shows the ^1H spectrum for a dispersion of a C_{14} lipid [dimeristoyl phosphatidyl choline (DMPC)] in the L_{α} phase, together with a theoretical, simulated spectrum.¹⁷ The broad, generally unresolved shape of the ^1H spectrum is typical

of that seen in macroscopically unoriented bilayer systems, and has a super-Lorentzian bandshape.⁴ The simulated spectrum of Wennerström et al. is based on equation (4) and assumes that the averaging results in a specific Gaussian bandshape for each class of protons, whose width is modulated by the $(3 \cos^2 \beta' - 1)$ term. The spectrum results from appropriately summing these contributions over all orientations β' . The three classes of proton assumed were those of the main chain methylene groups (including the glycerol headgroup), the chain terminal methyl groups and the headgroup methyl groups. The use of a common bandshape for the chain methylene protons is consistent with the roughly constant order profile for the chain methylene protons seen in the ^2H NMR of membranes.

A major advance in the general interpretation of the NMR of bilayers came from the early recognition by Chan and coworkers (see, for example, Bocian and Chan⁴) that the axially symmetric motions, particularly of the main chain methylene groups in the L_{α} phase, could be further decomposed into ‘fast’ and ‘slow’ types. The fast motions correspond to the expected timescale for *trans*–*gauche* isomerization in the chain ($\sim 10^{-10}$ s), while the slow motions describe a restricted reorientation of the whole chain about the direction of the local bilayer normal (the local averaging axis). This picture, which supplanted a number of earlier interpretations, arose from a consideration of the very different longitudinal (T_1) and transverse (T_2) relaxation rates seen for protons in bilayers, as well as the static spectral shape. Current interpretations of molecular motions in bilayers retain this basic view. Thus Seiter and Chan¹⁶ were able to demonstrate a reasonable simulation of the early component of the ^1H free induction decay from egg lecithin (mainly C_{18} , monounsaturated lipids) bilayer dispersions using this model. Only geminal proton interactions were considered, with essentially free rotation about a local chain axis, which could itself move randomly in a cone of half angle $\sim 50^\circ$ about the bilayer normal. While an evident simplification, this description is still semiquantitatively in accord with more recent interpretations (Section 5), at least in its essential statistical features. Following this, a number of detailed analyses of the general problem of dipolar interactions in systems with incomplete motional averaging have been presented, notably by Bloom and coworkers (for a review see Bocian and Chan⁴). However, the difficulty of uniquely ‘deconvoluting’ the ^1H powder pattern spectra to obtain molecular ordering information, such as is directly available from ^2H spectra, restricts the ultimate utility of these approaches.

A technique which addresses some of these difficulties in bilayer systems, while retaining the unique information content of ^1H NMR, is the use of wide-line, solid state NMR spectroscopy on macroscopically aligned, hydrated lipid bilayer samples. This has been pioneered by Cornell, Pope and coworkers (see, for example, Pope et al.¹⁸). Figure 2(a) shows their data for aligned DMPC multilayers in the $L_{\beta'}$, $P_{\beta'}$ and L_{α} phases. From equations (3) and (4) one expects the contribution to the resonance from any proton pair in an aligned sample to be a doublet, whose splitting scales as $\frac{1}{2}(3 \cos^2 \beta' - 1)$, where β' is equal to the angle between the sample stack normal and the magnetic field, θ , in cases where the motional averaging is symmetric about the membrane normal [see Figure 2(b)]. The spectra in Figure 2 are for $\theta = 0$. Unlike the case for unoriented lipid dispersions, partially resolved

Figure 2 (a) ^1H NMR spectra (90 MHz) from hydrated macroscopically oriented DMPC bilayers at temperatures 12°C ($L_{\beta'}$), 20°C ($P_{\beta'}$) and 28°C (L_{α}), showing resolved dipolar splittings (from Pope et al.¹⁸). Marker separations are 59 kHz (20°C) and 30 kHz (28°C) and the sample stack is oriented with its normal parallel to the main field B_0 . (b) Schematic picture (after Wennerström and Lindblom¹⁷) of a macroscopically aligned bilayer oriented at an angle θ' to the main field. For the L_{α} phase, $\beta' = \theta$, but for gel phase lipids $\beta' \neq \theta$, due to static tilt (see text)

splittings are observed in all three phases. These arise mainly from the chain methylene protons (methyl protons are near the spectrum center). From Figure 1(a), the total ^1H methylene splitting, $\Delta\nu_{\text{chain}}$, for an all-*trans* chain, averaging about the chain rotation axis, is $\sim 30 + 2 \times 22 \approx 75$ kHz. Additional interactions not included in Figure 1(a) will increase this value somewhat. It is known that there is a static ‘tilt’ angle between the chain axis and the membrane normal in the gel phases.¹ This is greater in the $L_{\beta'}$ than the $P_{\beta'}$ phase, which is reflected in the larger pattern splitting for the $P_{\beta'}$ phase [Figure 2(a)]. Pope et al. determined this angle to be $\sim 23^\circ$ for the $P_{\beta'}$ phase, from the angular dependence of the ^1H free induction decay in their system. Taking $\beta' = 23^\circ$, and the above 75 kHz estimate, a pattern width of ~ 58 kHz is expected for the $P_{\beta'}$ phase in Figure 2. This is plausibly close to the value seen, although there are clearly extra contributions in the wings of the spectrum from neglected interactions.

In the L_{α} phase, the spectrum narrows and sharpens dramatically. In this case the total chain motion is known to be symmetric about the bilayer normal (i.e. $\beta' = \theta$), but is composed of rapid intramolecular motions, modulated by a whole-chain ‘wobble’. The spectral narrowing due to the latter motion is referred to as the molecular or chain axis order

parameter, S_{α} (see, for example, Bocian and Chan,⁴ Section 5 and Figure 7). S_{α} may be independently estimated from ESR studies on cholestane spin probes in bilayers and is typically ~ 0.7 (see, for example, the discussion in Pace and Chan¹⁹). Since

$$\Delta\nu_{\text{obs}} = S_{\alpha} \Delta\nu_{\text{chain}} \quad (5)$$

where $\Delta\nu_{\text{obs}}$ and $\Delta\nu_{\text{chain}}$ are the observed and fast intramolecular-only chain averaged splittings, Figure 2(a) suggests that $\Delta\nu_{\text{chain}}$ is only ~ 40 kHz. This is a significant conclusion, from ^1H NMR, and indicates a major reduction of the all-*trans* ($\Delta\nu_{\text{chain}} \approx 75$ kHz) concentration in the L_{α} state (resulting in substantial loss of the ~ 44 kHz β - CH_2 interactions). Recent molecular dynamics simulation studies support this conclusion (see Section 5).

4 ^{19}F SPECTRA

Selective labeling of proton positions with ^{19}F is, in principle, a powerful tool for examining molecular processes in bilayers. Ho and colleagues (see, for example, Ho et al.⁵) have contributed substantially in this area, particularly with studies of ^{19}F labels in the acyl chains of lipids. The combination of both CSA and dipolar interaction derived information should provide a unique picture at the molecular level. The only concern is whether the larger fluorine atom perturbs the local molecular environment, either structurally or dynamically. The answer appears to be that it does quantitatively, but probably not qualitatively. In an elegant ^2H NMR experiment, Oldfield et al.²⁰ showed, by labeling lipid chains with both ^2H and ^{19}F , that the replacement of a CH_2 group by a CF_2 group increases the apparent disorder of neighboring CD_2 groups by $\sim 30\%$. Despite this, the study of ^{19}F substituted lipids in bilayers has proved very illuminating and worthwhile.

At typically used NMR field strengths (>3 T), the CSA interaction in the C–F bond dominates the ^{19}F spectrum in bilayers. Whenever axially symmetric motional averaging is present (which is essentially always the case), the first-order interaction Hamiltonian for the CSA, analogous to equations (3) and (4), is:⁵

$$\hat{\mathcal{H}}_{\text{CSA}} = \frac{3}{2} B_0 \hat{I}_z \cdot \left(\sum_i \overline{\sigma_{ii} S_{ii}} \right) \frac{1}{2} (3 \cos^2 \beta' - 1) \quad (6)$$

The S_{ii} order parameters are simply the motional averages of the quantities $\frac{1}{2}(3 \cos^2 \theta_i - 1)$, where θ_i is the angle between the i th ($i = x, y, z$) principal axis of the CSA tensor (in the local molecule fixed frame) and the axis about which averaging occurs. At present, the individual values of the σ_{ii} for a CF_2 group in a lipid chain are not known. However, the z molecular frame axis direction is very probably as indicated in Figure 1(a) (σ_{11}), and the value of the bracketed term in equation (6) (called the effective CSA, $\Delta\sigma$) is ~ 170 ppm for an all-*trans* chain undergoing rotational averaging about its long axis.⁵

In a CF_2 group, the F–F separation is 0.218 nm, giving a splitting of ~ 31 kHz, which is smaller than the geminal ^1H – ^1H value of ~ 60 kHz or the ^{19}F CSA splitting of ~ 50 kHz at high field (~ 300 MHz). Figure 3 shows ^{19}F spectra for dispersions of 2-(8,8- ^{19}F)DMPC in D_2O . In Figure 3(a),

Figure 3 (a) ^{19}F spectrum (282 MHz) of 8,8-difluoro-substituted DMPC in aqueous (D_2O) dispersion at 27°C (L_α phase): (. . .) experimental and (—) theoretical spectra assuming an axial CSA interaction with F–F and F–H dipolar interactions. (b) Dipolar ^{19}F NMR spectrum (40 MHz) of the same lipid obtained with CPMG pulse sequence to suppress chemical shift and heteronuclear dipolar interactions. (From Ho et al.⁵)

the full high field spectrum shows the characteristic axial CSA shape, with an evident axial dipolar (geminal F–F) contribution and some H–F dipolar broadening. The estimated $\Delta\sigma$ value is ~ 55 ppm. Even allowing for an S_α reduction [as in equation (5)] due to whole chain motion, this still implies a $\Delta\sigma_{\text{chain}}$ of only ~ 80 ppm, which is less than half the all-*trans* value (see the discussion in Section 3). Interactions linear in the spin operators of a given spin species (here ^{19}F), such as the CSA and heteronuclear dipolar interaction (here ^1H – ^{19}F), may be averaged to zero using pulse sequences of the CPMG type. Figure 3(b) shows the F–F dipolar-only spectrum resulting from such suppression (taken at 40 MHz to reduce CSA interaction). This has the classical Pake doublet shape for the powder pattern arising from an axially averaged dipolar interaction. The sharp peaks correspond to orientations with $\beta' = 90^\circ$, and their splitting gives the value of the total order parameter, $S = \frac{1}{2}[3\cos^2\beta'_b - 1]$, for the geminal F–F internuclear vector [equation (4)]. For an all-*trans* chain, $S = 0.5 S_\alpha$ (in magnitude) for either the F–F or C–D (from ^2H NMR) bond vectors (see section 5 and Figure 7. Figure 4 shows a comparison of the S_{FF} and S_{CD} order parameters as a function of temperature for labeled DMPC in the L_α phase.⁵ In general, S_{FF} is less than S_{CD} at the corresponding methylene position. Since the F–F (or H–H) and C–D vectors are geometrically inequivalent within the chain, there is no reason why their order parameters should be equal under conditions of partial motional averaging. The results of Oldfield et al.²⁰

Figure 4 Comparison of S_{FF} and S_{CD} as a function of fractional temperature increase above the melting temperature, T_c , for equivalently methylene disubstituted DPMC lipids. (•, ♦, ■) S_{FF} ; (x, +, *) S_{CD} . (•*) 4,4-Disubstituted; (♦+) 8,8-disubstituted; (■x) 12,12-disubstituted. All substitutions on the 2 chain. (Data from Ho et al.⁵)

suggest that S_{FF} underestimates the true S_{HH} by $\sim 30\%$, and so Figure 4 implies that S_{HH} is probably larger than S_{CD} . This is consistent with other estimates of these quantities (see, for example, the discussion in Pace and Chan²¹).

5 RELAXATION DATA

Studies of the frequency and orientational dependence of the various magnetic relaxation rates have proved to be one of the most illuminating applications of ^1H and ^{19}F NMR to the study of bilayers. Mostly these have involved measurements of the longitudinal relaxation times in the laboratory (T_1) and rotating frame ($T_{1\rho}$). In the systems of interest here, relaxation is governed by those components of the CSA and dipolar interactions which average to zero¹³ on a timescale short compared with the bulk magnetization relaxations. Generally that means time scales $\leq 10^{-4}$ s.

From Redfield theory one has^{8,21} the well-known contributions to the relaxation rates at nucleus, I ;

homonuclear dipolar interaction, r_{II} constant:

$$\frac{1}{T_1} = \frac{3}{4} v_I^2 [J_1(\omega_I) + 4J_2(2\omega_I)] \quad (7a)$$

$$\frac{1}{T_{1\rho}} = \frac{3}{4} v_I^2 \left[\frac{3}{2} J_0(\omega'_I) + \left(\text{terms} \simeq \frac{1}{T_1} \right) \right] \quad (7b)$$

CSA interaction:

$$\frac{1}{T_{1\rho}} = \nu_{\text{CSA}}^2 \left[\frac{1}{3} J_0(\omega_I') + \left(\text{terms} \simeq \frac{1}{T_1} \right) \right] \quad (7c)$$

where

$$\begin{aligned} \nu_{\text{CSA}} &= \frac{1}{4} \sqrt{6} \gamma_I B_0 \Delta\sigma \\ \nu_I &= (\gamma_I^2 \hbar / r_{II}^3)^2 \end{aligned} \quad (7d)$$

The ν terms are proportional to the characteristic magnitude of the interaction in each case; ν_H (geminal) = $1.55 \times 10^{10} \text{ s}^{-2}$, ν_F (geminal) = $4.11 \times 10^9 \text{ s}^{-2}$. The effective CSA, $\Delta\sigma$, in equation (7d) is that arising from fast intramolecular motion, but not chain axis motion. For the order plateau region of a lipid chain $\Delta\sigma$ is $\sim 80 \text{ ppm}$ in the L_α phase (Section 4). The $J_q(\omega)$ are the Fourier transforms of the autocorrelation functions, $G_q(\tau)$, of the zero averaging (as $\tau \rightarrow \infty$) components of the F_q terms in equation (1), (see, for example, Pace and Chan²¹). ω_I and ω_I' are the resonant frequencies in the laboratory and rotating frames, respectively. For simple processes characterized by a single correlation time, τ_c , $G(\tau) = G(0) \exp[-|\tau|/\tau_c]$ and so

$$J(\omega) = \int_{-\infty}^{\infty} G(\tau) \exp(-i\omega\tau) d\tau = G(0) \cdot \frac{2\tau_c}{1 + \omega^2\tau_c^2} \quad (8)$$

Because there is a range of molecular motional timescales contributing to $G_q(\tau)$ in the bilayer, the J_q terms do not have the simple ω dependences suggested by equation (8). Feigenson and Chan⁶ recognized this when they performed the first ω_H dependence studies of T_1 relaxation in lecithin bilayer dispersions. These data showed that at least two broad classes of motion were contributing, with τ_c values of $\sim 10^{-10}$ and 10^{-7} s . The fast motions were assumed to be intrachain isomerizations and the slow motions whole-chain reorientations. A subsequent analysis of the results²¹ indicated an approximate $\omega^{-1/2}$ dependence of T_1^{-1} for protons, and this has now been firmly established by Brown and coworkers as the dominating frequency power law for both ^2H and ^{13}C relaxation in bilayers (see *Bilayer Membranes: Deuterium and Carbon-13 NMR*).

Kimmich and Voigt,²² in an experimental tour de force, measured the ω_H dependence of proton T_1 in DPPC (C_{16} lipid), over the range 10^4 – 10^8 Hz . Figure 5 shows their data for L_α phase lipid dispersions. Not only are there extended regions showing $\omega_H^{-1/2}$ dependence, but there are evident transitions between these regions. Although there are several physical mechanisms that predict an $\omega^{-1/2}$ dependence of NMR relaxation rates, including linear defect ('kink') diffusion in ordered chains (such as seen in polyethylene²²), the most likely basis of the $\omega^{-1/2}$ observation in bilayer systems is the presence of liquid-crystal-like collective order fluctuations (see, for example, de Gennes²³). This is particularly true in the L_α phase, where, as has been shown, the intramolecular disorder is high, but kink diffusion processes may well contribute significantly below the phase transition. This matter is as yet unresolved.

Pace and Chan^{19,21} proposed a simple heuristic model of molecular motion in bilayers, inspired by the observations

Figure 5 Frequency dependences of the proton T_1 relaxation time in L_α phase aqueous (D_2O) DPPC (dipalmitoyl phosphatidyl choline) dispersion for temperatures 45° and 60°C . The solid lines show two regions of $\omega^{-1/2}$ relaxation rate behavior, with an evident two-step transition between these. Steps correspond to motional 'cutoffs' at $\omega_H \approx 6 \times 10^7$ and $2 \times 10^6 \text{ s}^{-1}$ (see text)

from ^2H NMR (see *Bilayer Membranes: Deuterium and Carbon-13 NMR*) that the L_α phase C–D order parameter profile is roughly constant over the first 10–12 chain methylene groups. This is shown in Figure 6(a) and assumes that, in the fluid state, the lipid chains adopt an alternating $tg^\pm tg^\pm$ or $g^\pm tg^\pm$ conformation, with the g bonds being approximately aligned with an average chain axis. Isomerizations ('crankshaft rotations') about these bonds are allowed, as they still permit the chain to be statistically 'confined' within a roughly cylindrical region; however, isomerizations about the 'horizontal' *trans* bonds are strongly disfavored. The chain axes may then undergo angular displacements about a local average position, as in liquid crystals. Although this model is clearly a simplified 'cartoon' of the actual events in lipid bilayers, it is interesting that recent realistic molecular simulations (see, for example, Pearce and Harvey²⁴) of these systems show typical chain configurations supporting the model, as well as exposing its limitations, particularly near the chain ends [Figure 6(b)]. An important feature of crankshaft-type models is that there are two disordered chain states, $g^\pm tg^\pm t \dots$, or $tg^\pm tg^\pm \dots$, and that interconversion between these is likely to be *slow* and proceed via an all-*trans* configuration.

Within a model like the above, it is possible systematically to decompose the relevant bond motions of the chain. This is illustrated in Figure 7. The bond vector is assumed to execute rapid, cylindrically symmetric motion about the instantaneous chain axis with order parameter, $S_\gamma = \frac{1}{2}(3 \cos^2 \beta_b - 1)$. The angle β_b is constant in the crankshaft geometry, but only approximately so in reality. The chain axis vector, $\mathbf{N}$, then executes restricted fluctuations about the local director (membrane normal) axis, $\mathbf{N}_0$, defined by polar angles α' , β' in the laboratory frame. This motion then defines the molecular order parameter, $S_\alpha = \frac{1}{2}(3 \cos^2 \beta'' - 1)$ within the model. The total order parameter is $S = S_\gamma S_\alpha$. The nonzero averaging interactions, referred to above, which do not contribute to relaxation, are simply those which remain projected along

Figure 6 (a) ‘Crankshaft’ model of the fluid lipid acyl chain configuration. Alternating *trans*–*gauche* configuration confines the chain to a roughly cylindrical region, and isomerizations ($g^{\pm} \leftrightarrow t \leftrightarrow g^{\pm}$) are permitted only for chain-axis-aligned (typically *gauche*) bonds. This imposes minimal packing disturbance on neighboring chains and allows these to execute liquid-crystal-type motions. Nongeminal dipolar interaction occurs mostly with a γ -methylene proton, as shown. (b) Typical molecular configurations from Langevin dynamics simulations of C_{16} lipids in a bilayer (from Pearce and Harvey²⁴). Configurations are mostly ‘disordered’ with some resemblance in the upper chain region to the model shown in (a). However, the simulations generally allow more types of disordered states than the crankshaft model predicts

the ‘static’ direction N_0 . In multilamellar dispersions and oriented samples, N_0 may be generally regarded as static on the NMR timescale, but in small vesicles, this is not so and all interactions average to zero.

The correlation times associated with *trans*–*gauche* isomerization (i.e. the γ motion in Figure 7) are $\sim 10^{-10}$ s. Hence these motions are all in the extreme narrowing NMR range ($\omega\tau_c < 1$), at least for the L_α phase bilayers. Under these circumstances, one obtains for the geminal H–H contribution to the ^1H methylene T_1 relaxation rate:²¹

$$\frac{1}{T_1} \simeq \frac{9}{8} (\gamma_H \hbar / r_{HH}^3)^2 (\tau_c + 1.02 S_\gamma^2 \cdot \zeta \omega_H^{-1/2}) \quad (9)$$

where τ_c is the correlation time for fast isomerization motions and the ζ term arises from treating the chain axis motion within the linearized nematic order formalism for liquid crystals:

$$\zeta \simeq (3kT/2\sqrt{2\pi})\eta^{1/2}K^{-3/2} \quad (10)$$

where K and η are average nematic elastic and viscosity constants. While the liquid crystalline phase of bilayers is not strictly a bulk nematic, an interpretation of bilayer motional

behavior in these terms appears still to be quantitatively reasonable.

At high ^1H frequency (> 200 MHz), the limiting intramolecular contribution to the ^1H relaxation in fluid bilayers is ~ 1 s⁻¹ (see Kroon et al.²⁵ and the discussion in Pace and Chan²¹). This corresponds to an apparent τ_c of $\sim 7 \times 10^{-11}$ s from equation (9). Direct estimates of τ_c from ^2H and ^{13}C labeled lipid data give $\tau_c \approx (3-4) \times 10^{-11}$ s. Thus nongeminal interactions contribute about 50% of fast proton intramolecular T_1 relaxation in bilayers. The observed rates are essentially the average methylene values, as these groups constitute the bulk of the protons in lipids and are the principal relaxation ‘sinks’ due to rapid spin diffusion in the system.²¹ At ^1H frequencies below ~ 100 MHz, the nematic term in equation (9) begins to dominate the relaxation. Its value depends upon S_γ^2 , the projection of the geminal H–H bond vector motion onto the local chain axis direction. This is ~ 0.2 (0.25 in the crankshaft model), and a reasonable estimate for ζ is $\sim (2-3) \times 10^{-6}$ s^{1/2} for fluid DPPC.^{14,19} equation (9) then semiquantitatively predicts (within $\sim 50\%$) the observed T_1 behavior for fluid DPPC (Figure 5) in the limiting low-frequency regime ($\nu < 10^5$ Hz), but underestimates the rate by a factor of ~ 4 at high ($> 10^7$ Hz) frequency, although the $\omega^{1/2}$ power law dependence is evident in both limiting regions. An apparent ‘two-step’ transition occurs between these regions in Figure 5. The first, at which $\omega_H \approx 6 \times 10^7$ s⁻¹ (10^7 Hz) clearly corresponds to lipid lateral diffusion (timescale $\tau_d \sim 10^{-8}$ s).¹⁴ Over times less than τ_d (i.e. $\omega_H > 1/\tau_d$), nematic motions modulate unaveraged intermolecular dipolar interactions—which produce a total T_1^{-1} contribution comparable to the total intramolecular processes in this region. When $\omega_H > 1/\tau_d$, the intermolecular motions contribute only a constant T_1^{-1} component [roughly proportional to τ_d , see equation (8)], which is of diminishing relative magnitude as ω_H drops. The surprising result from Figure 5 is that there is a further distinct ‘cut-off’ at $\sim 4 \times 10^5$ Hz (corresponding to $\tau_c \approx 4 \times 10^{-7}$ s). This can only be of intramolecular origin, and represents a slow motion which largely averages out all remaining nongeminal dipolar interactions.

An important insight into this slow process comes from $T_{1\rho}$ measurements on oriented bilayers, both for ^1H and ^{19}F . Rotating frame relaxation is sensitive to molecular motions in the 10^{-5} – 10^{-6} s range, as $\omega' \approx 10^5$ s⁻¹. Figure 8 shows the data of Pope et al.¹⁸ and of Ho and co-workers⁸, for the angular dependence of $T_{1\rho}$ in aligned lipid multilayers. Because of the similar forms of equations (7b) and (7c), the angular dependence of the nematic fluctuation contribution to $T_{1\rho}$ is the same for ^1H and ^{19}F . This is proportional to $(\sin \beta' \cos \beta')^2$, i.e. to the square of the derivative of $(3 \cos^2 \beta' - 1)$ [this is evident from considering Figure 7(c), but see Ho and coworkers⁸ and Pace and Chan²¹]. Such a dependence is seen in liquid crystals.²⁶ Figures 8(a) and 8(b) show, however, that the ^1H and ^{19}F $T_{1\rho}$ relaxation is dominated by a component roughly proportional to $(3 \cos^2 \beta' - 1)^2$. Furthermore, this component was essentially absent from the ^2H $T_{1\rho}$ angular dependence of perdeuterated lipids.¹⁸ Thus the relaxation mechanism must involve a modulation of the magnitude of residual nongeminal intramolecular dipolar interaction directed along the chain axis, not any large-scale angular motion of the chain itself, which would also reflect in deuterium $T_{1\rho}$. The most likely basis of this modulation is

Figure 7 Decomposition of bond vector motions for methylene groups in chains. (a) Fast, symmetric axial motion of the bond vector about the instantaneous chain axis is assumed, with order parameter $S_\gamma = \frac{1}{2}(3\cos^2\beta_b - 1)$. (b) β_b is constant in the crankshaft model for a particular intramethylene interaction. (c) The chain axis then executes limited motion (nematic fluctuation) about a local 'fixed' axis (normal to the membrane plane), N_0 . This latter motion defines the molecular order parameter $S_\alpha = \frac{1}{2}(3\cos^2\beta'' - 1)$ and is associated with a wide range of motional timescales. The total order parameter is $S = S_\gamma S_\alpha$.

the slow interconversion of (surprisingly) long lived average chain configurations, each possessing a distinct, residual intramolecular order. For example, the average nongeminal interactions between a particular methylene proton and its individual neighbors [particularly γ -methylene protons, see Figure 6(a)] are different in the two crankshaft states, although the actual events in the bilayer are likely to be more complex than this simple picture suggests. From measurements at several rotating frame frequencies, the correlation time, τ_i , for the relaxation was estimated as $\sim 10^{-6}$ s (protonated lipids) and $> 10^{-5}$ s (difluoro-substituted lipids). The protonated lipid value is generally consistent with the above estimate from unoriented dispersions (-4×10^{-7} s), but the fluorinated lipid value is much longer, presumably reflecting a slowing of the interconversion in this system due to steric hindrance from the fluorine atoms on the chain. Although the natures of the molecular processes underlying the data given in Figure 8 are yet to be fully resolved, the results graphically demonstrate the power of ^1H and ^{19}F NMR to reveal quite unanticipated results in partially ordered systems.

6 VESICLES AND HIGH RESOLUTION

Ultrasonic irradiation (sonication) of aqueous dispersions of phospholipids produces sealed, single walled bilayer vesicles (radius, $R \approx 10.0$ – 15.0 nm), whose NMR spectra show medium–high resolution features (see *Sonicated Membrane Vesicles*). In these systems nuclear dipolar and chemical shift anisotropies are averaged to zero on the timescale of vesicle tumbling, which is normally faster than $\sim 10^{-5}$ s. For this reason, most of the earlier high-resolution NMR studies on

bilayers utilized vesicles as the membrane model (see, for example, Bocian and Chan⁴).

Small vesicles are kinetically but not thermodynamically stable, reverting over hours or days into larger bilayer aggregates. The high surface curvature, particularly for the inner lipid layer, raises some questions concerning their quantitative similarity to 'flat', stable bilayers. The answer appears to be that for the outer monolayer at least (which constitutes $\sim 70\%$ of the material), the lipids are in a similar environment to that of a flat bilayer, but with somewhat more motional disorder. The high-frequency (100 kHz) proton T_1 values are virtually the same (0.3 s) in DPPC bilayers (Figure 5) and vesicles²⁵ at 50°C . By varying the suspending solution viscosity, Mackay et al.²⁷ showed that most of the proton linewidth for small vesicles arose from a term proportional to the net correlation time, τ_v , for vesicle tumbling, plus lateral diffusion of lipids around the vesicle surface. These and other ^2H results on vesicles (see Pace and Chan²¹) appeared to contradict the conclusions of Bocian and Chan⁴ that chain disorder, arising from local processes, was greater in vesicles than in bilayers, due to the high vesicle surface curvature. However, it was subsequently shown²¹ that when the chain-axis fluctuations were treated as motions in a two-dimensional nematic medium, the linewidth expression took the form:

$$\Delta\nu_{\text{H}} = \frac{1}{\pi T_2} \approx \frac{9}{8\pi} \nu_{\text{H}}^2 S_\gamma^2 Z_v(0) + \left(\text{terms} \approx \frac{1}{T_1} \right) \quad (11)$$

where $Z_v(0)$ is given by

$$Z_v(0) = \frac{2\tau_v}{5} \left(1 - \frac{3kT}{\pi K'} \ln \frac{R}{d} \right) \quad (12)$$

Figure 8 Angular dependence [see Figure 2(b)] of rotating frame relaxation ($T_{1\rho}$) rates in aligned fluid multilayer samples. (a) Data of Pope et al.¹⁸ for ^1H relaxation in egg lecithin (mostly C_{18} PC) at ω_{H}' values of 9.4×10^4 ($\circ$) and 3.2×10^5 ($\square$) s^{-1} . (b) Data of Ho and coworkers⁸ for 8,8-difluoro-substituted DMPC, $\omega_{\text{F}}' = 5.1 \times 10^4$ s^{-1} . Curves are theoretical fits assuming mostly a $(3 \cos^2 \beta' - 1)^2$ dependence (see text). The larger magnitude of this effect in the fluorolipid arises from the ~ 10 -fold longer correlation time associated with the relaxation motion in this case (see text)

Here K' is the average two-dimensional nematic force constant and d is approximately equal to the lipid molecule chain diameter (~ 0.5 nm). The significance of equation (11) is that essentially the *whole* interaction (tumbling plus nematic motions) scales as τ_v . This happens because the nematic fluctuations are continuously distributed on all timescales down the 'cutoff' imposed by overall vesicle motion, τ_v . The bracketed expression in equation (12) may be thought of as the square of an effective vesicle S_α term. From the observed $\Delta\nu_{\text{H}}$ value of ~ 60 Hz for small ($R \approx 10.0$ nm, $\tau_v \approx 4.7 \times 10^{-7}$ s) C_{18} vesicles,²⁸ S_α is ~ 0.58 , which is significantly smaller than the value of >0.7 for bilayers of the same material. This also corresponds to a K' value substantially smaller than for bilayer dispersions (see Pace and Chan^{19,21}). Thus the main difference revealed by these studies between the lipids in bilayers and vesicles (outer layer mostly) is that the chain

Figure 9 360 MHz static and magic angle spinning (MAS) ^1H Fourier transform NMR spectra of a potassium oleate ($\sim 70\%$ in D_2O) L_α phase dispersion. (a) Static spectrum at 26°C ; (b) 2.7 kHz MAS NMR spectrum; (c) expansion of the centerband region of (b); (d) solution spectrum (micellar) of potassium oleate in D_2O . (From Forbes et al.¹⁰)

packing is 'looser' in the vesicle, leading to larger chain-axis fluctuations, but with no evidence of a significant difference in chain internal order. For the inner layer, this is probably not so. Certainly, average chemical shift differences occur between the inner and outer monolayers in vesicles and the resonance lines from the inner monolayer are narrow.²⁸

Equation (4) shows that one way to minimize dipolar broadening in bilayers is to use aligned multilamellar samples, oriented to the main field at the 'magic angle', $\beta' = 54.7^\circ$ (whence $\frac{1}{2}[3 \cos^2 \beta' - 1] = 0$). This has been used (see, for example, van der Leeuw and Stulen²⁹) and produces spectra with at least the resolution obtainable from vesicles. However, the technique has not been as widely employed for ^1H studies on bilayers, as has been the case for other nuclei (^{31}P and ^{13}C , for example). Preparation of suitably aligned sample stacks is not straightforward and special (usually solid state) NMR probes must be used. Another approach is to induce the averaging required by equation (4) using MAS. This also requires special probes, but dilute, unoriented samples may be used. This technique was first applied to ^1H NMR of bilayers by Chapman et al.³⁰ and has recently been revived by Oldfield and coworkers.¹⁰ Figure 9 shows typical results obtained with potassium oleate, illustrating the impressive line narrowing achieved. The interesting feature here is that the sample spinning frequency is < 3 kHz, which is not technically demanding for modern instruments. Oldfield et al. demonstrated that the resolution was sufficient that two-dimensional NMR techniques, such as cross relaxation (NOESY) which has also been applied to vesicles,⁹ could usefully be employed. The fact that dilute, unoriented samples may be used means that the MAS approach is likely to prove increasingly useful in the study of such areas as membrane-drug, membrane-protein, etc.,

interactions. This is the most likely future direction for ^1H and ^{19}F NMR applications to bilayer systems, particularly when combined with heteronuclear techniques such as chemical shift correlation spectroscopy (see, for example, Lee and Griffin¹¹).

1 INTRODUCTION

The effects of chemical exchange, including transverse relaxation and magnetization transfer, have long been of interest in NMR spectroscopy (see **Chemical Exchange Effects on Spectra**, Volume 2 and **Relaxation Effects of Chemical Exchange**, Volume 6). Exchange phenomena in solution NMR spectroscopy arise when chemical or conformational kinetic processes render the isotropic chemical shifts of nuclear spins time-dependent, either by transferring the spins between distinct sites or by altering the local magnetic environment of the spins. Kinetic processes on times scales ranging from μs to s are effective in causing chemical exchange effects. Many biological processes occur with time constants within this range, and numerous applications have been reported that utilize chemical exchange effects to characterize time-dependent processes in biological macromolecules.^{1–20}

The present article describes a subset of ZZ-exchange,^{21,22} lineshape,^{23,24} Carr–Purcell–Meiboom–Gill (CPMG),^{25,26} and $R_{1\rho}$ ^{27,28} relaxation techniques that are sensitive to molecular motions or chemical kinetic processes on μs – s time scales in biological macromolecules. The experimental techniques, rather than specific applications, will be emphasized. In most cases, pulse sequences suitable for application to isolated $I_n\text{S}$ ($I = {}^1\text{H}$; $X = {}^{15}\text{N}$ or ${}^{13}\text{C}$; $n = 1, 2$, or 3) spin systems are presented. The pulse sequences shown do not

include details of solvent suppression techniques because different approaches are used for ${}^1\text{H}$, ${}^{13}\text{C}$, and ${}^{15}\text{N}$.^{29,30} Compensatory rf fields should be applied during the recycle delay to ensure that the same average rf power is deposited into the sample for all values of the relaxation period.³¹ The pulse sequences illustrated use INEPT elements for polarization transfer; in some cases, increased sensitivity can be obtained by replacing the INEPT transfers with heteronuclear cross polarization or CPMG-INEPT methods with large effective fields.^{32–34}

2 TWO-SITE CHEMICAL EXCHANGE

For simplicity, only two-site exchange will be considered. The nucleus of interest is assumed to exchange between two magnetically distinct environments A and B while the system remains at chemical equilibrium throughout the NMR experiment. Furthermore, the present article focuses on situations in which scalar coupling constants are not perturbed by the exchange process (see **Chemical Exchange Effects on Spectra**, Volume 2); consequently, the modified Bloch or McConnell equations are sufficient to describe the effect of exchange (see **Relaxation Effects of Chemical Exchange**, Volume 6). The kinetic scheme is:

in which k_1 and k_{-1} are forward and reverse rate constants and the chemical exchange rate constant, k_{ex} , is given by,

$$k_{ex} = k_1 + k_{-1} = \frac{k_1}{p_B} = \frac{k_{-1}}{p_A} \quad (2)$$

$p_A \geq 0.5$ and $p_B = 1 - p_A$ denote the equilibrium populations of equivalent nuclear spins in species A and B. Higher order chemical reactions, such as ligand binding or oligomerization, are treated by defining k_1 and k_{-1} as pseudo-first-order rate constants. The resonance frequencies in the rotating frame for spins in site A and B are Ω_A and Ω_B , respectively, in units of angular frequency, and the chemical shift difference between the two sites is $\Delta\omega = \Omega_B - \Omega_A$. The total equilibrium magnetization is M^0 , and the equilibrium longitudinal magnetization at each site is $M_A^0 = p_A M^0$ and $M_B^0 = p_B M^0$. The longitudinal relaxation rate constants of the sites in the absence of exchange (resulting from dipolar, shielding anisotropy (CSA), and quadrupolar relaxation) are R_{1A}^0 and R_{1B}^0 . The transverse relaxation rate constants of the sites in the absence of exchange are R_{2A}^0 and R_{2B}^0 .

The effect of exchange on free-precession lineshapes has been discussed in **Relaxation Effects of Chemical Exchange**, Volume 6. The relative values of k_{ex} and $\Delta\omega$ define the limits of what is commonly referred to as “fast” and “slow” exchange on the chemical shift time scale:

$$\begin{aligned} k_{ex} < \Delta\omega & \quad \text{Slow exchange} \\ k_{ex} \approx \Delta\omega & \quad \text{Intermediate exchange} \\ k_{ex} > \Delta\omega & \quad \text{Fast exchange} \end{aligned} \quad (3)$$

In the slow exchange limit, resolved lines are observed for the two sites with resonance frequencies Ω_A and Ω_B . The effect of exchange is to shift the resonance positions and broaden the lines until the lines coalesce in the intermediate exchange regime (a more exact analysis yields the result that coalescence occurs when $2(p_A p_B)^{1/2} \Delta\omega \approx k_{ex}$). In the fast exchange limit, a single averaged resonance line is observed at the population-weighted average shift, $\Omega = p_A \Omega_A + p_B \Omega_B$.

3 IDENTIFYING SPINS AFFECTED BY CHEMICAL EXCHANGE

The initial step in characterizing a kinetic process by NMR spectroscopy is identifying spins subject to chemical exchange. If p_B is sufficiently large and exchange is slow on the chemical shift time scale, then additional resonances arising from the second species are observed in the NMR spectra. These resonances usually are identified during initial efforts to obtain sequence specific resonance assignments. NOESY, ROESY, and ZZ-exchange spectroscopy, discussed below, are used to confirm that the additional resonances arise from chemical exchange processes. However, only a single set of resonances are observed in the NMR spectra if exchange is fast on the chemical shift time scale or if p_B is sufficiently low that the minor component is not observable in the slow exchange limit. In such circumstances, exchange effects are recognized by an increase in the transverse relaxation rate constant relative to the value expected for dipolar, quadrupolar and CSA interactions for the observed resonance signals:

$$R_2 = R_2^0 + R_{ex} \quad (4)$$

in which R_2^0 refers to either the relaxation rate constant for an individual site (for slow exchange) or to the population averaged relaxation rate constant (for fast exchange) and R_{ex} is the excess contribution to R_2 due to exchange.

R_2 in equation (4) can be approximated either by R_2^* , the free-precession damping constant including effects of magnetic field inhomogeneity, or by R_{2echo} , the damping constant observed for a Hahn spin echo experiment. The value of R_2^* is obtained from the resonance full-width at half-height linewidth, $\Delta\nu_{1/2}$, using $R_2^* = \Delta\nu_{1/2}/\pi$ or equivalently, from the decay of the time domain free induction decay or interferogram (in multidimensional NMR spectra).³⁵ The size of the inhomogeneity contribution to R_2^* can be estimated using spins not affected by the exchange process. The value of R_{2echo} is obtained using the sequence $t - 180^\circ - t$ incorporated into either a one-dimensional or multidimensional NMR experiment.³⁶ The 180° pulse must be selective to refocus scalar coupling interactions. If spectra are recorded for $t = 0$ and $t = \tau$, then $R_{2echo} = (2\tau)^{-1} \ln[I(0)/I(\tau)]$, in which $I(t)$ is the intensity of the resonance measured for an echo time t . The echo time, τ , should be long enough that $\tau k_{ex} \gg 1$; otherwise, the effects of exchange on the echo decay are partially suppressed. Complete expressions for the echo decay are given in **Relaxation Effects of Chemical Exchange**, Volume 6. In either approach, additional decoupling sequences may need to be applied during the free-precession evolution period or during the spin-echo delay to prevent evolution into antiphase coherences subject to additional relaxation mechanisms.^{37,38}

The value of R_2^0 is obtained by one of the following approaches: (1) analysis of R_1 , R_2 and NOE data for ^{13}C or ^{15}N spins using the model free formalism;^{39,40} (2) use of the magnetic field dependence of R_2 to determine $J(0)$, the spectral density function at zero frequency;^{41–43} and (3) use of ^1H -X dipole/X CSA relaxation interference rate constants.^{43,44}

The first method determines the rotational diffusion tensor for the molecule using R_1 , R_2 and NOE relaxation rate constants for spins not subject to conformational exchange broadening (see **Protein Dynamics from NMR Relaxation**, Volume 6). Once the diffusion tensor for the molecule is known, R_2^0 for individual exchange broadened nuclear spins is approximated using the measured values of R_1 and NOE. This method is automated in software programs such as ModelFree.³⁹ Residues subject to exchange broadening must be carefully distinguished from residues affected by rotational diffusion anisotropy in order to obtain an accurate assessment of the diffusion tensor.^{44–46}

Most investigations of molecular dynamic properties of macromolecules through spin relaxation measure R_2 using CPMG experiments with a single spin echo delay, τ_{cp} , satisfying $1/\tau_{cp} \geq 1000 \text{ s}^{-1}$ or $R_{1\rho}$ experiments with an effective field in the rotating frame, ω_e , satisfying $\omega_e \geq 12000 \text{ s}^{-1}$ to partially suppress exchange effects.⁴⁷ Under these conditions, the residual R_{ex} contribution to R_2 is proportional to B_0^2 , in which B_0 is the static magnetic field strength, for all exchange time scales.⁴⁸ Using this result, the second approach defines:^{42,43}

$$\begin{aligned} \Gamma &= R_2 - \frac{1}{2}R_1 - \left(\frac{3d^2}{4}\right)J(\omega_H) \\ &= \left(\frac{d^2}{2}\right)J(0) + \left(\frac{2}{9}\gamma_C^2\Delta\sigma^2J(0) + \Theta_{ex}\right)B_0^2 \end{aligned} \quad (5)$$

in which $d = (\mu_0 h \gamma_H \gamma_X) / (8\pi^2 r_{XH}^3)$; μ_0 is the permeability of free space; h is Planck's constant; γ_H and γ_X are the gyromagnetic ratios for ^1H and X spins, respectively; r_{XH} is the distance between the two nuclei; Θ_{ex} is a constant of proportionality; $\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp}$; and the principal components of the X spin CSA tensor are $\sigma_{\parallel}$ and $\sigma_{\perp}$. The value of $J(\omega_H)$ is obtained from the heteronuclear NOE by reduced spectral density mapping methods.⁴⁹ The value of $J(0)$ is obtained from the intercept of a linear least squares fit of Γ versus B_0^2 . Once $J(0)$ is determined, values of R_2^0 at each value of B_0 can be obtained by setting $\Theta_{ex} = 0$ in equation (5).

The third method only is applicable to nuclear spins, such as backbone amide ^{15}N spins in proteins, with substantial CSA contributions to laboratory frame relaxation. Interference between the ^1H -X dipolar and X CSA interactions constitutes an additional relaxation mechanism that is unaffected by chemical exchange (see **Relaxation Effects Involving Cross Correlation in Biomolecules**). The transverse cross-correlation relaxation rate constant, η_{xy} , represents cross-relaxation between in-phase and antiphase magnetization, while the longitudinal cross-correlation relaxation rate constant, η_z , represents cross-relaxation between longitudinal magnetization and two-spin order. For an axially symmetric chemical shift tensor, the cross-correlation rate constants are:⁵⁰

$$\begin{aligned} \eta_z &= -\sqrt{3}cdP_2(\cos\beta)J(\omega_X) \\ \eta_{xy} &= -\frac{\sqrt{3}}{6}cdP_2(\cos\beta)[4J(0) + 3J(\omega_X)] \end{aligned} \quad (6)$$

Figure 1 Identifying chemical exchange in BPTI. Shown is a graph of $R_{2echo} - R_2^0$ versus the protein sequence. Regions of pronounced chemical exchange linebroadening, for which $R_{ex} = R_{2echo} - R_2^0 \gg 0$, are evident in the vicinity of the Cys 14–Cys 38 disulfide bond

in which $c = 3^{-1/2} \gamma_X B_0 \Delta\sigma$, β is the angle between the symmetry axes of the chemical shift and dipole tensors, and $P_2(x) = (3x^2 - 1)/2$. If both η_{xy} and η_z have been measured,^{44,51} then:⁴³

$$R_2^0 = \left(R_1 - \frac{7}{4} J(\varepsilon \omega_H) \right) \frac{\eta_{xy}}{\eta_z} + \frac{13}{8} J(\xi \omega_H) \quad (7)$$

which does not require assumptions about the values of $\Delta\sigma$ and β . If only η_{xy} has been measured, but $\Delta\sigma$ and β are known, then:

$$R_2^0 = \left(\frac{3d^2 + 4c^2}{4\sqrt{3}cd P_2(\cos \beta)} \right) \eta_{xy} + \frac{13}{8} d^2 J(\xi \omega_H) \quad (8)$$

The value of ε is 0.92 in equation (7) and ξ is 0.96 in equations (7) and (8) for ^{15}N .

An example of the use of R_{2echo} and R_2^0 for detecting chemical exchange broadened backbone amide ^{15}N resonances is provided for basic pancreatic trypsin inhibitor (BPTI) in Figure 1. Values of R_{2echo} were measured using a Hahn spin-echo sequence incorporated into an in-phase ^{15}N – ^1H HSQC experiment.^{36,52} WALTZ-16 decoupling was used during the spin echo period to suppress evolution of the ^{15}N – ^1H scalar coupling interaction.⁵³ Values of R_2^0 were obtained from η_{xy} using equation (8) and η_{xy} was measured using established techniques.⁴³ Significant values of $R_{ex} = R_{2echo} - R_2^0$ are observed for residues near the Cys 14 to Cys 38 disulfide linkage.^{48,54}

4 ZZ-EXCHANGE SPECTROSCOPY

Slow chemical exchange processes can be studied by monitoring the exchange of longitudinal magnetization between sites if the population of the minor site B is large enough to generate observable resonance signals.⁵⁵ In addition, k_{ex} must not be much less than R_{1A} and R_{1B} ; otherwise, the signals decay due to relaxation faster than population transfer. Investigations of chemical exchange using ^1H NMR spectroscopy

are complicated by the coexisting transfer of magnetization through the nuclear Overhauser effect, although the opposite signs of the NOE and ROE for macromolecules can be used to approximately suppress magnetization transfer through dipolar relaxation.⁵⁶ Isotopic enrichment of macromolecules enables X-nucleus ZZ-exchange to be utilized instead of ^1H magnetization transfer. Although either exchange of longitudinal magnetization^{57,58} or two-spin order^{57,59} can be monitored, longitudinal relaxation is much slower for ^{15}N and ^{13}C spins than for ^1H spins in macromolecules; consequently, the relaxation rate constant for two-spin order is less favorable than for X-nucleus longitudinal magnetization. For biological macromolecules, X-nucleus R_1 values typically are on the order of 1 s^{-1} ; consequently, ZZ-exchange measurements are applicable to chemical exchange processes with $k_{ex} < 10^2 \text{ s}^{-1}$.

A three-dimensional ^1H –X– ^1H pulse sequence for a ZZ-exchange measurement is shown in Figure 2; as described in the figure caption, either ^1H – ^1H or X– ^1H two-dimensional pulse sequences can be derived from the three-dimensional sequence and employed if the resonances due to exchanging spins are sufficiently well-resolved.^{58,60} The evolution of longitudinal magnetization during the mixing time, t , is described by the modified Bloch or McConnell equations:⁶¹

$$\frac{d}{dt} \begin{bmatrix} \Delta M_{zA}(t) \\ \Delta M_{zB}(t) \end{bmatrix} = \begin{bmatrix} -R_{1A}^0 - p_B k_{ex} & p_A k_{ex} \\ p_B k_{ex} & -R_{1B}^0 - p_A k_{ex} \end{bmatrix} \begin{bmatrix} \Delta M_{zA}(t) \\ \Delta M_{zB}(t) \end{bmatrix} \quad (9)$$

Figure 2 Three-dimensional pulse sequence for ZZ-exchange NMR spectroscopy.⁵⁸ Narrow and wide bars depict 90° and 180° pulses respectively. All pulses are x-phase unless otherwise indicated. Decoupling during the relaxation delay to suppress heteronuclear dipole–dipole cross relaxation and dipole/CSA cross correlation can be performed using WALTZ-16⁵³ or a train of ^1H 180° pulses at 5 ms intervals. Decoupling during acquisition is achieved with the GARP sequence.⁹² Delays are $\Delta = 1/(4J_{XH})$, $t_1^a = (1 - t_1/t_{1max})\Delta$, $t_1^b = (1 - 2\Delta/t_{1max})t_1/2$, $t_1^c = \Delta + t_1/2$, t_{1max} is the maximum value of the t_1 labeling period, $t_2^a = (1 - t_2/t_{2max})\Delta$, $t_2^b = (1 - 2\Delta/t_{2max})t_2/2$, $t_2^c = \Delta + t_2/2$, t_{2max} is the maximum value of the t_2 labeling period, and t is the mixing time. A two-dimensional X– ^1H correlation spectrum is obtained by setting $t_1^a = t_1^c = \Delta$ and $t_1^b = 0$; a two-dimensional ^1H – ^1H correlation spectrum is obtained by setting $t_2^a = t_2^c = \Delta$ and $t_2^b = 0$. The phase cycle is $\phi_1 = x, -x$; $\phi_2 = 4(x), 4(-x)$; $\phi_3 = x, x, y, y, -x, -x, -y, -y$; and receiver = $x, -x, -x, x$. The gradients are used to suppress unwanted coherences and pulse imperfections.⁹³ Frequency discrimination during t_1 and t_2 is obtained by shifting the phase of ϕ_1 and ϕ_2 , respectively, and the receiver according to the States-TTPI protocol.⁹⁴ As discussed in the text, magnetization transfer during the periods a-b and c-d may need to be considered in addition to the mixing time t

in which $\Delta M_{zA}(t) = M_{zA}(t) - M_A^0$ and $\Delta M_{zB}(t) = M_{zB}(t) - M_B^0$. The solution of this equation is:

$$\begin{bmatrix} \Delta M_{zA}(t) \\ \Delta M_{zB}(t) \end{bmatrix} = \begin{bmatrix} a_{AA}(t) & a_{AB}(t) \\ a_{BA}(t) & a_{BB}(t) \end{bmatrix} \begin{bmatrix} \Delta M_{zA}(0) \\ \Delta M_{zB}(0) \end{bmatrix} \quad (10)$$

in which,

$$\begin{aligned} a_{AA}(t) &= \frac{1}{2}[(1 - \Lambda) \exp(-\lambda_- t) + (1 + \Lambda) \exp(-\lambda_+ t)] \\ a_{BB}(t) &= \frac{1}{2}[(1 + \Lambda) \exp(-\lambda_- t) + (1 - \Lambda) \exp(-\lambda_+ t)] \\ a_{AB}(t) &= \frac{k_{ex} p_A}{\lambda_+ - \lambda_-}[(\exp(-\lambda_- t) - \exp(-\lambda_+ t))] \\ a_{BA}(t) &= \frac{k_{ex} p_B}{\lambda_+ - \lambda_-}[(\exp(-\lambda_- t) - \exp(-\lambda_+ t))] \end{aligned} \quad (11)$$

and,

$$\begin{aligned} \Lambda &= \frac{R_{1A}^0 - R_{1B}^0 + k_{ex}(p_B - p_A)}{\lambda_+ - \lambda_-} \\ \lambda_{\pm} &= \frac{1}{2}\{R_{1A}^0 + R_{1B}^0 + k_{ex} \\ &\quad \pm [(R_{1A}^0 - R_{1B}^0 + k_{ex}(p_B - p_A))^2 + 4p_A p_B k_{ex}^2]^{1/2}\} \end{aligned} \quad (12)$$

Thus, the intensity of the autpeak for site A (site B) evolves as $a_{AA}(t)$ ($a_{BB}(t)$), and the crosspeak between A and B (B and A) evolves as $a_{AB}(t)$ ($a_{BA}(t)$).

Crosspeak intensity can be observed at $t = 0$ if exchange is fast enough to transfer magnetization between sites during the INEPT periods. If ^1H magnetization is frequency labeled during t_1 , then exchange effects must be considered between points a-b and c-d in Figure 2. If only X magnetization is frequency labeled, during t_2 , then exchange effects must be

considered between points c-d in Figure 2. The effects of exchange during the INEPT periods can be approximated by including the length of the INEPT sequences, 2Δ , in the mixing time provided that $|R_{1A}^0 - R_{1B}^0| \ll k_{ex}$ and $|R_{2A}^0 - R_{2B}^0| \ll k_{ex}$ for the X nucleus and $|R_{2A}^0 - R_{2B}^0| \ll k_{ex}$ for the ^1H spin. If these conditions do not hold, then the effects of exchange during the INEPT periods must be analyzed numerically. If a three-dimensional experiment is performed, then exchange during the t_2 evolution period must be analyzed numerically unless $t_{2max} k_{ex} \ll 1$.

Two-dimensional ^{15}N ZZ-exchange experiments have been used to quantify chemical exchange between folded and unfolded forms of the drk SH3 domain.^{14,29} Typical results are shown in Figure 3. The data were analyzed using equations (10)–(12) to determine the relaxation rate constants for the folded (site A) and unfolded forms (site B) of the protein and the folding (k_{-1}) and unfolding (k_1) rate constants.

5 LINESHAPE ANALYSIS

Lineshape analysis is a classical approach for analyzing exchange processes in NMR spectroscopy.^{23,24} Applications to proteins include chemical exchange arising from folding,^{12,62,63} ligand binding,⁶⁴ and oligomerization.¹³ In each of these applications, the lineshapes can be altered by varying experimental parameters, such as temperature, ligand concentration, denaturant concentration, or protein concentration, which enables a global analysis of lineshapes to be performed as functions of the adjustable parameters. Typically, lineshape analysis is applicable to exchange processes in biological macromolecules with $k_{ex} < 10^4 \text{ s}^{-1}$.

For transverse coherence subject to free precession under the Zeeman Hamiltonian, the evolution of the magnetization is described by the modified Bloch or McConnell equations:^{61:}

$$\begin{aligned} \frac{d}{dt} \begin{bmatrix} M_A^+(t) \\ M_B^+(t) \end{bmatrix} &= \begin{bmatrix} -i\Omega_A - R_{2A}^0 - p_B k_{ex} & p_A k_{ex} \\ p_B k_{ex} & -i\Omega_B - R_{2B}^0 - p_A k_{ex} \end{bmatrix} \\ &\times \begin{bmatrix} M_A^+(t) \\ M_B^+(t) \end{bmatrix} \end{aligned} \quad (13)$$

The solution of these equations is:

$$\begin{bmatrix} M_A^+(t) \\ M_B^+(t) \end{bmatrix} = \begin{bmatrix} a_{AA}(t) & a_{AB}(t) \\ a_{BA}(t) & a_{BB}(t) \end{bmatrix} \begin{bmatrix} M_A^+(0) \\ M_B^+(0) \end{bmatrix} \quad (14)$$

in which $M_A^+(t) = M_{Ax}(t) + iM_{Ay}(t)$, $M_B^+(t) = M_{Bx}(t) + iM_{By}(t)$,

$$\begin{aligned} a_{AA}(t) &= \frac{1}{2}[(1 - \Lambda) \exp(-\lambda_- t) + (1 + \Lambda) \exp(-\lambda_+ t)] \\ a_{BB}(t) &= \frac{1}{2}[(1 + \Lambda) \exp(-\lambda_- t) + (1 - \Lambda) \exp(-\lambda_+ t)] \\ a_{AB}(t) &= \frac{k_{ex} p_A}{\lambda_+ - \lambda_-}[(\exp(-\lambda_- t) - \exp(-\lambda_+ t))] \\ a_{BA}(t) &= \frac{k_{ex} p_B}{\lambda_+ - \lambda_-}[(\exp(-\lambda_- t) - \exp(-\lambda_+ t))] \end{aligned} \quad (15)$$

Figure 3 ^{15}N ZZ-exchange data for Thr 12 of the drk SH3 domain.²⁹ $I_{ij}(t)$ is the integrated peak volume as a function of the mixing time T . ($\bullet$) $I_{AA}(t) = \Delta M_{zA}(0)a_{AA}(t)$ and ($\blacksquare$) $I_{BB}(t) = \Delta M_{zB}(0)a_{BB}(t)$ are the volumes of the autocorrelation peaks and ($\circ$) $I_{BA}(t) = \Delta M_{zA}(0)a_{BA}(t)$ and ($\square$) $I_{AB}(t) = \Delta M_{zB}(0)a_{AB}(t)$ are the volumes of the crosspeaks. The lines are the optimized fits to equations (10)–(12). The fitted results yield $R_{1A}^0 = 2.41 \pm 0.05 \text{ s}^{-1}$, $R_{1B}^0 = 1.90 \pm 0.11 \text{ s}^{-1}$, $k_1 = 0.86 \pm 0.06 \text{ s}^{-1}$, and $k_{-1} = 0.43 \pm 0.03 \text{ s}^{-1}$. and,

$$\Lambda = \frac{-i\Delta\omega + R_{2A}^0 - R_{2B}^0 + k_{ex}(p_B - p_A)}{\lambda_+ - \lambda_-}$$

$$\lambda_{\pm} = \frac{1}{2}\{-i\Omega_A - i\Omega_B + R_{2A}^0 + R_{2B}^0 + k_{ex} \pm [(-i\Delta\omega + R_{2A}^0 - R_{2B}^0 + k_{ex}(p_B - p_A))^2 + 4p_A p_B k_{ex}^2]^{1/2}\}$$
(16)

The NMR spectrum is given by the Fourier transformation of $M_A^+(t) + M_B^+(t)$. Computer optimization of the parameters in equations (14)–(16) is utilized to fit the experimental lineshapes. In practical applications, particularly for ^1H lineshapes, the magnetization components in equations (14)–(16) should

Figure 4 Lineshape analysis for folding of λ repressor. The aromatic regions of the ^1H NMR spectra of the monomeric Gly 46 Ala/Gly 48 Ala mutant of λ repressor (residues 6–85) at 30 °C are shown for urea denaturant concentrations of (a) 0 M, (b) 2.2 M, (c) 4.1 M, (d) 5.1 M, (e) 7.0 M, and (f) 8.9 M. Expansions of the (g) experimental and (h) fitted ^1H aromatic spectra also are shown for λ repressor in 4.1 M urea. (Reproduced with permission from *J. Biomol. NMR*, 1998, **11**, 355–359)

be regarded as representing individual resonance lines of scalar coupled multiplets. If scalar coupling constants are modulated by the exchange process, then the more general theoretical approach described in **Chemical Exchange Effects on Spectra**, Volume 2 is required.

Folding of the Gly 46 Ala/Gly 48 Ala mutant of monomeric λ repressor has been investigated as a function of urea denaturant concentration by Oas and coworkers using ^1H one-dimensional spectroscopy.⁶² The aromatic regions of a series of NMR spectra are shown in Figure 4 to illustrate the changes in lineshape observed as the urea concentration is increased from 0 to 8.9 M. Figure 4(h) and (g) compare the experimental and fitted lineshapes for a single urea concentration of 4.1 M. Data were analyzed using the program ALASKA to fit k_1 (unfolding) and k_{-1} (folding) assuming values of other spectral parameters for folded and unfolded species obtained from the spectra recorded at 0 and 8.9 M urea, respectively.⁶² In most cases, lineshape analyses have been restricted to one-dimensional ^1H spectra; however, two-dimensional lineshape analysis using X– ^1H heteronuclear correlation spectroscopy yields increased spectral resolution, provides lineshape information for both the ^1H and X spins, and exhibits simplified lineshapes in indirect frequency dimensions because heteronuclear scalar coupling interactions are easily decoupled. As an example, ^{15}N – ^1H HSQC spectroscopy has been used in a lineshape analysis of the dimerization of the protein barstar.¹³

6 $R_{1\rho}$ ROTATING FRAME RELAXATION METHODS

In an $R_{1\rho}$ experiment, magnetization is spin-locked in the rotating frame by application of a radio-frequency field.^{27,28} The relaxation rate constant for the component of the magnetization along the direction of effective field in the rotating frame is called $R_{1\rho}$ and depends on the amplitude, ω_1 , and frequency, ω_{rf} , of the applied radiofrequency field. The effective field in the rotating frame is $\omega_e = (\Omega^2 + \omega_1^2)^{1/2}$ in which $\Omega = p_A\Omega_A + p_B\Omega_B$ is the population-average chemical shift, and the tilt angle of the effective field is given by $\tan \theta = \omega_1/\Omega$. $R_{1\rho}$ experiments are sensitive to chemical exchange processes if values of ω_e near k_{ex} are achievable experimentally. Typically, $R_{1\rho}$ experiments are limited to values of $k_{ex} < 10^5 \text{ s}^{-1}$. Sample heating and limitations on the maximum value of ω_1 tolerated by the spectrometer probe and amplifiers during sustained spin-locking pulses are the principal experimental constraints on ω_e . Furthermore, exchange processes with $k_{ex} > 10^5 \text{ s}^{-1}$ result in small exchange linebroadening unless $\Delta\omega$ is very large. $R_{1\rho}$ measurements on biological macromolecules can be performed using near-resonance (often called on-resonance for convenience)⁶⁵ or off-resonance^{66–68} rf fields. In the former case, the rf transmitter frequency is positioned close to the resonances of interest (or in the middle of the NMR spectrum) and the minimum value of ω_1 is large enough to ensure that $\theta > 70^\circ$ over the spectral region of interest. The relaxation dispersion curve is obtained by varying ω_1 . In the latter case, the rf transmitter is positioned far enough off-resonance to ensure that $\theta < 70^\circ$. The relaxation dispersion curve is obtained by varying ω_1 or the carrier offset or both in order to vary ω_e .

A pulse sequence for an off-resonance $R_{1\rho}$ experiment for X spins is shown in Figure 5(a)^{66–68} and a pulse sequence

Figure 5 Pulse sequences for (a) X-nucleus and (b) ^1H -nucleus $R_{1\rho}$ experiments.^{65–68,71} Narrow and wide bars depict 90° and 180° pulses respectively. All pulses are x-phase unless otherwise indicated. Decoupling during acquisition is achieved with the GARP sequence.⁹² The unlabeled gradients are used to suppress unwanted coherences and pulse imperfections.⁹³ Delays are $\Delta = 1/(4J_{XH})$, $t_1^a = \Delta + t_1/2$, t is the relaxation delay, and δ is longer than the duration of the gradients applied during δ . (a) The spin-lock rf frequency is set outside the spectral region of interest. The adiabatic sweep A rotates z-magnetization to the direction of the effective field and the adiabatic sweep B rotates the spin-locked magnetization back to the z-axis.^{66,68} The phase cycle is $\phi_1 = x, -x$; $\phi_2 = 4(x), 4(-x)$; $\phi_3 = x, x, y, y, -x, -x, -y, -y$; $\phi_4 = x$; receiver = $x, -x, -x, x$. Gradient coherence selection are achieved with gradients Gd and Ge. Echo/antiecho signals are recorded in separate experiments by inverting the amplitude of Gd and phase ϕ_4 .⁹⁵ The ϕ_1 and the receiver phases are inverted for each t_1 increment to shift axial peaks to the edge of the spectrum.⁹⁴ (b) The spin-lock rf frequency is positioned in the center of the spectral region of interest, and $\chi = 1/(2\omega_1)$ serves to align the magnetization along the direction of the effective field.⁹⁶ The phase cycle is $\phi_1 = x, -x$; $\phi_2 = 4(x), 4(-x)$; $\phi_3 = x, x, -x, -x$; and receiver = $x, -x$. Frequency discrimination is obtained by shifting the phase of the receiver and ϕ_1 according to the States-TTPI protocol⁹⁴

for a near-resonance $R_{1\rho}$ experiment for ^1H spins is shown in Figure 5(b).^{69,70} The pulse sequence in Figure 5(b) is applicable to ^1H spins that do not have significant homonuclear scalar coupling interactions; for example, the $^3J_{N\alpha}$ scalar coupling interaction is eliminated in uniformly $^{15}\text{N}/^2\text{H}$ enriched proteins.⁷¹

$R_{1\rho}$ experiments have been applied principally to characterize kinetic processes in the fast-exchange limit ($k_{ex}/\Delta\omega \gg 1$) using the theoretical expression:^{27,28,72}

$$R_{1\rho}(\omega_e) = R_2^0 \sin^2 \theta + R_1 \cos^2 \theta + \sin^2 \theta \frac{\Phi_{ex} k_{ex}}{k_{ex}^2 + \omega_e^2} \quad (17)$$

in which R_2^0 and R_1 are population-averaged relaxation rate constants and $\Phi_{ex} = p_A p_B \Delta\omega^2$. Other expressions applicable

outside of the fast-exchange limit have been derived, but have not been applied yet to relaxation in proteins.^{72,73} The dependence of $R_{1\rho}$ on R_1 in equation (17) can be removed either by the constant-relaxation time approach⁶⁷ or by independently measuring R_1 . The number of independent parameters in equation (17) can be further reduced either by measuring R_2^* ³⁵ or R_2^0 .⁷

The folding equilibrium of the peripheral subunit binding domain (PSBD) from the dihydrolopoamide acetyltransferase component of the pyruvate dehydrogenase multienzyme complex from *Bacillus stearothermophilus* has been characterized using ^{15}N $R_{1\rho}$ measurements.⁷ R_1 was measured independently and R_2^0 was obtained from measurements of η_{xy} using equation (8) in order to express R_{ex} as

$$R_{ex} = \frac{R_{1\rho}}{\sin^2 \theta} - \frac{R_1}{\tan^2 \theta} - R_2^0 = \frac{\Phi_{ex} k_{ex}}{k_{ex}^2 + \omega_e^2} \quad (18)$$

The relaxation dispersion curve is linearized by plotting $1/R_{ex}$ versus ω_e^2 , as shown in Figure 6(a). Values of $k_{ex} = (b/m)^{1/2}$ and $\Phi_{ex} = (mb)^{-1/2}$ are obtained from the slope m and intercept b .⁷⁴ In the fast-exchange limit, p_A , p_B , and $\Delta\omega$ cannot be obtained separately from Φ_{ex} by fitting the relaxation dispersion. However, Φ_{ex} and Ω are related by $\Phi_{ex} = -\Omega^2 + a\Omega - b$ in which $a = \Omega_A + \Omega_B$ and $b = \Omega_A \Omega_B$. If Φ_{ex} and Ω are measured as a function of temperature

Figure 6 ^{15}N $R_{1\rho}$ relaxation dispersion for Ala 11 of PSBD. (a) Data recorded at 304 (○), 313 (▲), and 323 K (▽).⁷ R_{ex} data for Ala 11 were obtained from equation (18), values of R_1 and η_{xy} were measured by conventional approaches,^{29,44} and values of R_2^0 obtained from η_{xy} using equation (8). The best least squares fitted line is drawn for each data set. (b) Φ_{ex} is plotted versus the isotropic shift Ω at each temperature. The solid line is the best fit to determine the x-intercepts $\Omega_A = 118.80 \pm 0.02$ ppm and $\Omega_B = 126.7 \pm 0.4$ ppm with $\Delta\omega = 7.9 \pm 0.4$ ppm. (c) Arrhenius plot for (○) folding (k_{-1}) and (●) unfolding (k_1) rate constants. The apparent activation barriers are 17 ± 14 kJ mol $^{-1}$ for folding and 125 ± 19 kJ mol $^{-1}$ for unfolding

and Ω_A and Ω_B are assumed to be independent of temperature, then the coefficients a and b can be determined by least squares optimization. Subsequently, $|\Delta\omega| = (a^2 - 4b)^{1/2}$, and $\Omega_{A,B} = [a \pm (a^2 - 4b)^{1/2}]/2$. Once $\Delta\omega$ is known, p_A , p_B , k_1 , and k_{-1} are obtained from Φ_{ex} and k_{ex} at each temperature. An example of this analysis is shown in Figure 6(b); the temperature dependence of the rate constants obtained from this analysis is shown in Figure 6(c). The chemical shift of the (unobserved) unfolded PSBD species is determined to be 126.7 ± 0.4 ppm; this value is in good agreement with the predicted random coil chemical shift of 126.0 ppm for an Ala residue preceded by a Tyr residue.⁷⁵

7 CPMG RELAXATION METHODS

In a CPMG experiment, the relaxation of transverse magnetization is observed during a $(\tau - 180^\circ - 2\tau - 180^\circ - \tau)_n$ spin-echo sequence, in which $\tau_{cp} = 2\tau$ is the spacing between 180° pulses and n is an integer.^{25,26} CPMG experiments are sensitive to chemical exchange processes if values of $1/\tau_{cp}$ near k_{ex} are achievable experimentally. CPMG experiments in proteins typically are applicable to chemical exchange processes with values of $k_{ex} < 10^4 \text{ s}^{-1}$ as a result of experimental constraints on the minimum value of τ_{cp} . Sample heating at high pulsing rates is a major experimental limitation. In addition, theoretical analyses of relaxation during CPMG experiments assume that the refocusing pulses have negligible duration;^{76–78} at pulse duty cycles $> 10\%$, this assumption may not be valid.⁶⁶ The maximum value of τ_{cp} for CPMG experiments applied to X spins is limited by evolution under the one-bond heteronuclear scalar coupling Hamiltonian, which interconverts in-phase and antiphase magnetization during the spin-echo period. The relaxation rate constant for heteronuclear antiphase magnetization includes a contribution from longitudinal relaxation of the coupled ^1H spin and is greater than the rate constant for in-phase magnetization. To minimize contributions from antiphase magnetization, $\tau_{cp} < 1/(4J_{XH})$, where J_{XH} is the one-bond heteronuclear scalar coupling constant; therefore, the maximum values of τ_{cp} are 1.7 ms for ^{13}C and 2.6 ms for ^{15}N .

The range of τ_{cp} values that can be utilized is expanded by CPMG experiments designed to average in-phase and antiphase magnetization. Relaxation-compensated CPMG pulse sequences for IS,⁷⁹ I₂S,⁸⁰ and I₃S⁸¹ are shown in Figure 7. In these experiments, in-phase and antiphase coherences are interchanged during the period U in order to eliminate any τ_{cp} -dependent effects arising from differential relaxation rates. Conventional CPMG pulse sequences for measuring R_2 are self-compensating for evolution of the scalar coupling if $\tau_{cp} = m/J_{XH}$, in which m is an integer.⁴⁸ Hahn spin echo measurements, self-compensated CPMG experiments and relaxation-compensated CPMG experiments can be used in combination to cover the widest possible range of τ_{cp} values.⁴⁸ For I₂S and I₃S spin systems, relaxation is multiexponential and constant relaxation time experiments are necessary to obtain accurate results.^{80,81}

These approaches are illustrated in Figure 8 for residue Cys 38 in BPTI at temperatures of 300 and 313 K.⁴⁸ The backbone ^{15}N resonance of Cys 38 is broadened as a result of isomerization of the Cys 14–Cys 38 disulfide bond. The

Figure 7 Pulse sequences for relaxation-compensated CPMG experiments in (a) IS, (b) I₂S, and (c) I₃S spin systems.^{48,79} Narrow and wide bars depict 90° and 180° pulses respectively. All pulses are x-phase unless otherwise indicated. Decoupling during acquisition is achieved with the GARP or WALTZ-16 sequences.^{53,92} Delays are $\tau = \tau_{cp}/2$, $\Delta = 1/(4J_{XH})$, and $\delta > \text{Gd}$. In (a) $t_1^a = \Delta + t_1/2$; in (b) $\varepsilon = 1/(8J_{XH})$, $t_1^a = \zeta + t_1/2$, and $\zeta > \text{Ge}$; and in (c) $\zeta = 1/(10J_{XH})$. In (a) and (b), the phase cycle is $\phi_1 = x, -x$; $\phi_2 = 4(x), 4(-x)$; $\phi_3 = x, x, y, y, -x, -x, -y, -y$; $\phi_4 = x$; receiver = $x, -x, -x, x$. The unlabeled gradients are used to suppress unwanted coherences and pulse imperfections.⁹³ Gradient coherence selection are achieved with gradients Gd and Ge. Echo/antiecho signals are recorded in separate experiments by inverting the amplitude of Gd and phase ϕ_4 .⁹⁵ The ϕ_1 and the receiver phases are inverted for each t_1 increment to shift axial peaks to the edge of the spectrum.⁹⁴ In (c), the phase cycle is $\phi_1 = x, -x$; $\phi_2 = 2(x), 2(-x)$; $\phi_3 = 8(x), 8(-x)$; $\phi_4 = 4(x), 4(y), 4(-x), 4(-y)$; receiver = $x, -x, -x, x, -x, x, x, -x$. The unlabeled gradients are used to suppress unwanted coherences and pulse imperfections.⁹³ Frequency discrimination during t_1 is obtained by shifting the phase of ϕ_2 and the receiver according to the States-TTPI protocol⁹⁴

values of $R_2(1/\tau_{cp})$ were acquired using the pulse sequence of Figure 7(a) for values of $\tau_{cp} < 10$ ms, a self-compensated pulse sequence for $\tau_{cp} = 10.8$ and 21.5 ms, and a Hahn-echo

Figure 8 Global analysis of chemical exchange for the ^{15}N spin of Cys 38 in BPTI. Values of $R_2(1/\tau_{cp})$ at (●) $B_0 = 11.7$ T and (○) $B_0 = 14.1$ T are shown at temperatures of (a) 300 K and (b) 313 K. At 300 K, fitting with equation (19) yields $p_A = 0.953 \pm 0.004$, $\Delta\omega = 8.9 \pm 0.4$ ppm, $k_{ex} = 380 \pm 70$ s $^{-1}$ and $R_2^0 = 8.6 \pm 0.1$ s $^{-1}$. At 313 K, fitting with equation (21) yields $\Phi_{ex} = 0.108 \pm 0.024$ ppm 2 , $k_{ex} = 1300 \pm 290$ s $^{-1}$, and $R_2^0 = 6.4 \pm 0.7$ s $^{-1}$

pulse sequence for $\tau_{cp} = 64.5$ ms.⁴⁸ Dispersion data were fit with a general expression for the transverse relaxation rate constant for site A ($p_A > p_B$), $R_2(1/\tau_{cp})$ given by,^{28,77,82}

$$R_2\left(\frac{1}{\tau_{cp}}\right) = R_2^0 + \frac{k_{ex}}{2} - \frac{1}{2\tau_{cp}} \cosh^{-1} [D_+ \cosh(\eta_+) - D_- \cos(\eta_-)] \quad (19)$$

in which,

$$D_{\pm} = \frac{1}{2} \left[\pm 1 + \frac{\Psi + 2\Delta\omega^2}{(\Psi^2 + \zeta^2)^{1/2}} \right] \quad (20)$$

$$\eta_{\pm} = \frac{\tau_{cp}}{\sqrt{2}} \left[\pm \Psi + (\Psi^2 + \zeta^2)^{1/2} \right]^{1/2}$$

$\Psi = k_{ex}^2 - \Delta\omega^2$ and $\zeta = 2\Delta\omega k_{ex}(p_B - p_A)$ and identical relaxation rates R_2^0 have been assumed for the two sites. In the fast-exchange limit, equation (19) is approximated by,⁸³

$$R_2\left(\frac{1}{\tau_{cp}}\right) = R_2\left(\frac{1}{\tau_{cp}} \rightarrow \infty\right) + \frac{\Phi_{ex}}{k_{ex}} \left[1 - \frac{2}{k_{ex}\tau_{cp}} \tanh\left(\frac{k_{ex}\tau_{cp}}{2}\right) \right] \quad (21)$$

and R_2^0 is the population-average value. The static magnetic field dependence of exchange linebroadening indicates that the exchange time scale is intermediate at 300 K and approaches the fast limit at 313 K. Consequently, dispersion curves recorded at two static magnetic field strengths were analyzed globally using equations (19) for data acquired at 300 K and equation (21) for data acquired at 313 K. Analysis of data recorded at a single static magnetic field or data recorded for a limited range of τ_{cp} values can give substantial systematic errors.^{48,79} Simultaneous analysis of both CPMG and $R_{1\rho}$ data has been proposed to increase the range of accessible effective fields and robustness of the data analysis.^{5,10}

The pulse sequences shown in Figure 7 average the relaxation rate constants for in-phase and antiphase magnetization; consequently, R_2^0 in these sequences is larger than the in-phase relaxation rate constant and contains contributions from ^1H longitudinal relaxation. For IS spin systems, relaxation periods for two-spin order can be incorporated into the pulse sequence of Figure 5(a) to remove the contributions to $R_2(1/\tau_{cp})$ from ^1H longitudinal relaxation.⁸⁴ For ^{15}N spins, this method facilitates the use of relaxation interference rate constants to determine R_2^0 [equations (7) and (8)] and enables faster kinetic processes to be investigated by CPMG methods. Wüthrich and coworkers have shown that significantly narrower NMR signals can be obtained for one component of the ^{15}N - ^1H scalar-coupled doublet from cancellation of ^1H - ^{15}N dipole-dipole and ^{15}N CSA interactions (see **Transverse Relaxation-optimized NMR Spectroscopy with Biomacromolecular Structures in Solution**).⁸⁵ Recently, CPMG pulse sequences have been modified to select the narrow TROSY doublet component during the relaxation period, the indirect labeling period, and the detection period.^{71,86,87} These modifications facilitate the quantification of exchange linebroadening contributions in larger macromolecules because the relative conformational exchange contribution to the phenomenological relaxation rate constant during the CPMG period is enhanced and the improved resolution and sensitivity of TROSY ^1H - ^{15}N correlation spectra are obtained.

8 CHEMICAL EXCHANGE IN MULTIPLE QUANTUM SPECTROSCOPY

If two spins are affected by the same chemical exchange kinetic process, then the chemical shift changes for the two spins resulting from transitions between sites will be correlated. This correlation gives rise to exchange effects that can either broaden or narrow resonance lineshapes for multiple quantum coherences.⁸⁸ In essence, for multiple quantum coherences, the value of $\Delta\omega$ in the equations given above should be replaced by the difference in multiple quantum frequencies, $\Delta\omega_{MQ}$; thus, for double (DQ) and zero (ZQ) quantum coherences, respectively, $\Delta\omega_{DQ} = \Delta\omega_I + \Delta\omega_S$ and $\Delta\omega_{ZQ} = \Delta\omega_I - \Delta\omega_S$, in which $\Delta\omega_I$ ($\Delta\omega_S$) is the chemical shift difference between sites A and B for the I (S) spin. Hahn spin-echo pulse sequences for measuring the difference between the relaxation rate constants for DQ and ZQ quantum coherences have been developed for ^1H - ^{15}N backbone amide moieties⁸⁹ and for $^{13}\text{C}^\alpha$ - $^{13}\text{C}^\beta$ moieties⁹⁰ in proteins. The sign of the difference between DQ and ZQ relaxation rate constants gives the relative sign of the chemical shift differences for ^1H and ^{15}N spins. This information, which cannot be obtained

from single quantum experiments, is helpful for mechanistic interpretations of exchange phenomena. In some cases, selection of the narrower of the DQ or ZQ coherences (depending on the relative chemical shifts) results in improved resolution and sensitivity of multidimensional NMR spectra.^{88,91}

9 CONCLUSIONS

Chemical exchange effects in NMR spectroscopy provide information on conformational and chemical kinetic processes occurring in biological macromolecules on biologically-relevant time scales. Experimental methods described in this article enable chemical exchange constants, k_{ex} , to be determined over a range from 0.1 to 10^5 s^{-1} using ZZ-exchange, lineshape, CPMG, and $R_{1\rho}$ methods. Applications of these techniques promise to enhance understanding of the biological function of kinetic processes on μs -s time scales in proteins and other biological macromolecules.

1 INTRODUCTION

High-resolution solid state ^{13}C NMR spectroscopy has been used extensively to analyze the conformation, dynamics, and molecular order of biological and model membrane systems. With improvements in magnet technology, the mid 1970s saw ^{13}C NMR used for a broad range of studies of biological membrane systems under natural abundance conditions.¹ As a spin- $\frac{1}{2}$ nucleus of intermediate abundance (1.1%), ^{13}C is suitable for investigations employing both isotopically enriched and natural abundance samples. The large chemical shift range provided by ^{13}C NMR and the sensitivity enhancement possible from cross polarization (CP) to neighboring protons permits the acquisition of well-resolved solid state ^{13}C NMR spectra from both biomembranes and model lipid bilayer systems.

As a fundamental constituent of natural membrane bilayers, lipid dispersions have been widely studied as model membranes. From the ^{13}C static powder spectra of membrane lipids, many of the resonances in the hydrocarbon chain, the carbonyl positions, the headgroup, and the glycerol backbone regions can be resolved. Line broadening due to the dipolar interaction with the abundant protons can be overcome by decoupling. Resolution can be enhanced with magic angle spinning (MAS) and applied to both model and cell membranes. Alternatively, multibilayers may be macroscopically aligned on glass slides or magnetically oriented to improve resolution (see Figure 1). Each magnetically equivalent site gives a single resonance, and measurements taken at a range of sample orientations relative to the magnetic field direction permit the observation of the ^{13}C chemical shift anisotropy (CSA),^{2,3} which is normally unresolved in the static powder pattern.

A number of physical techniques including ^1H and ^{13}C NMR of ultrasonically dispersed lipid vesicles, ^2H NMR of deuterated lipids, and ^{31}P NMR of lipid headgroups^{4,5} have shown that within lipid bilayers and biological membranes, lipid molecules undergo rapid conformational and long-axis rotation reorientation. This anisotropic motion results in incomplete averaging of anisotropic nuclear interactions such as dipolar and shielding anisotropy tensors, necessitating the use of solid state NMR techniques. Since MAS can average the residual of these interactions, high-resolution ^{13}C

Figure 1 Natural abundance ^{13}C CP NMR spectrum of an aligned lipid bilayer, egg yolk phosphatidylcholine dispersed in water. The bilayer normal is perpendicular to the magnetic field, and the resonances from the lipid carbonyls, double bonds, glycerol region, headgroup methyls, chain methylenes, and terminal methyl are well resolved

NMR spectra can be obtained from unsonicated multibilayer dispersions⁶ and intact biological membranes.⁷ It has been demonstrated that the resolution of ^{13}C MAS NMR spectra of phospholipid bilayers can be equal to that of sonicated samples.^{8,9} Membranes contain several components in addition to phospholipids, including proteins, peptides, and steroids. To determine structural parameters of membrane proteins and polypeptides, specific isotopic labeling is usually required.

2 BIOMEMBRANE AND MODEL MEMBRANE STUDIES

Phospholipids are the major lipid component found in biomembranes, and consequently, phospholipid bilayers are commonly used as model membranes. When dispersed in water phospholipids form multilamellar, lyotropic, liquid crystals with a random distribution of bilayer orientations. If the dispersion is subjected to ultrasonic irradiation, these structures break down into small, unilamellar vesicles. The reorientation of these vesicles in solution results in substantial cancellation of the static dipolar and anisotropic chemical shielding interactions, resulting in ^{13}C spectra that are resolved in isotropic chemical shift. The first reported observation of high-resolution NMR spectra from a model membrane was by Chapman and Penkett.¹⁰ Early ^{13}C NMR investigations of membrane systems included studies of unsonicated multibilayers with and without cholesterol^{11,12} and rat liver mitochondrial membranes.¹³ Natural abundance ^{13}C relaxation rates were measured for pure phospholipid bilayers above the phase transition temperature.¹⁴ The ^{13}C

relaxation rates were found to decrease as the terminal methyl is approached from the glycerol backbone.

2.1 CP Studies

Early ^{13}C NMR studies employing CP to study powder patterns of lipid bilayers and membranes,^{15,16} showed that after the severe broadening of the ^{13}C – ^1H dipole interactions was removed by decoupling, the unsonicated lipid multilayers still displayed a residual linewidth resulting from the unaveraged ^{13}C CSA. The dynamics of phospholipids has been analyzed in terms of the conformation and order at the lipid–water interface by studies of the ^{13}C CP powder pattern of the carbonyl groups at the 1 and 2 positions of phosphatidylcholine in multilamellar dispersions.^{17,18} The headgroup mobility and the rotational correlation times in the acyl chain region of membrane lipids has been measured using ^{13}C NMR over a range of temperatures spanning the L_β , P_β , and the L_α phases of the lipid dispersion.¹⁹

The incorporation of cholesterol was found to broaden the chain resonances of phospholipids in multilamellar dispersions.²⁰ The interaction of phospholipids with cholesterol²¹ and the membrane-bound polypeptide gramicidin A²² was examined using CP ^{13}C NMR. These compounds were found to introduce a long correlation time component to the motion of the lipid molecules, as evident in the shortening of $T_{1\rho}^H$, and to order the motion, as determined from the increased CSA of the 1-carbonyl site. Carbon-13 NMR has been used in conjunction with ^{31}P NMR to gain further insight into dynamic and structural details of gramicidin–phospholipid phase formation.²³

Cross polarization ^{13}C NMR has been used to study the motion of the carbonyl groups and the phase behavior of mixed chain phosphatidylcholines,²⁴ and to characterize motionally restricted molecules in normal human erythrocytes.²⁵ The rotating frame relaxation time, $T_{1\rho}^H$, of membranes appears to be dominated by contributions from cooperative molecular or segmental motions on the millisecond to microsecond timescale.²⁶ The effect of glycophorin from human erythrocyte membranes on the dynamics of lipids in phospholipid vesicles was found to be similar.^{27,28} Subsequently, using ^{13}C relaxation measurements, the incorporation of retinal was found to result in a reduction of mobility in the lipid acyl chain²⁹ region. The dynamics of various chemical groups in anhydrous bacteriorhodopsin membranes was characterized using ^{13}C CP MAS spectra.³⁰ More recent work employing ^{13}C CP MAS has been performed using hydrated phospholipid dispersions,^{31–33} and illustrates the usefulness of ^{13}C NMR for the study of model membrane systems. The interaction of cytochrome *c* with cardiolipin bilayers was investigated using ^{13}C CP NMR, natural abundance lipid, and specifically labeled protein.³⁴

2.2 Non-CP Studies

Cross polarization is not always necessary in hydrated samples because the T_1^C values are sufficiently short. Carbon-13 NMR was used to measure the outside/inside bilayer distribution and translocation of phospholipids in mixed sonicated vesicles.³⁵ The ^{13}C chemical shifts and T_1 relaxation

times of chloroplast lipid extracts were reported³⁶ in 1977, and later applied to the study of molecular order within chloroplast membranes.³⁷ Carbon-13 NMR spectroscopy has been used to determine the headgroup conformation of phospholipids.^{38,39} The integrity of large unilamellar vesicles made from ^{13}C -labeled phosphatidylcholine was demonstrated using shift reagents that affected the outer lipid monolayer headgroups.⁴⁰ Using ^{13}C T_1 measurements, cholesteryl esters were shown to reduce the mobility of phospholipids.⁴¹ In liposomes or vesicles made from polar lipid extracts of *Halobacterium halobium*,⁴² a sharp change in molecular motion was detected at the lipid phase transition by ^{13}C NMR.

The mobility of ^{13}C -enriched human myelin basic protein reconstituted in multilayer liposomes⁴³ was reported in 1980. Specific ^{13}C labeling of the choline group of phospholipids in erythrocyte, endoplasmic, and sarcoplasmic reticulum membranes was used to study the phases of membrane lipids.⁴⁴ By employing ^{13}C -enriched enkephalin, an opioid peptide, its binding to phosphatidylserine was monitored by changes in chemical shift and T_1 measurements.⁴⁵ Evidence for lipid-associated chlorophyll in whole spinach thylakoid membranes⁴⁶ was verified with ^{13}C NMR spectroscopy. Using a simple spin echo, the powder pattern of phosphatidylcholine, ^{13}C -labeled at the 2-carbonyl, was recorded as a function of temperature, both below and above the lipid main phase transition temperature.⁴⁷ Further work has shown ^{13}C NMR to be a useful technique for defining phases in pure and mixed phospholipid systems,^{24,48–50} and for studying lipid–steroid interactions.^{51,52}

Carbon-13 T_1 relaxation rates and ^{13}C – ^1H nuclear Overhauser effects (NOE) reported in 1992, revealed little difference in the lipid acyl chain dynamics between small and large unilamellar vesicles.⁵³ In addition, the lateral diffusion of lipid molecules in phospholipid vesicles has been estimated from ^{13}C spin–spin relaxation time, T_2 , measurements.⁵⁴ Using magnetically aligned phosphatidylcholine–detergent mixtures, solid state ^{13}C NMR has yielded high-resolution spectra. From the measured chemical shift anisotropies and dipolar splittings in these systems structural and dynamic information has been derived, such as the headgroup orientation of alkyl glycosides at a lipid bilayer interface.^{55,56}

2.3 MAS Studies

A study of the dynamics of the lipids in phospholipid–rhodopsin powders and in whole retinal rod disk membranes using ^{13}C MAS, demonstrated that rhodopsin reduces the rate of high-frequency motions.^{57,58} Similar results were obtained with bacteriorhodopsin in lipid bilayers⁵⁹ using static, ^{13}C , solid state NMR and CP. High-resolution CP MAS was used to determine the dynamic behavior of the resolved ^{13}C resonances of anhydrous bacteriorhodopsin membranes,³⁰ and the lipid, protein, and bacteriochlorophyll *a* of intracytoplasmic membrane and the light-harvesting complex of photosynthetic bacteria.⁶⁰

MAS techniques were employed to determine the spin–lattice relaxation times, T_1 , of individual carbons in unsonicated phospholipid dispersions.⁶¹ In addition, well-resolved ^{13}C MAS spectra have been obtained from erythrocyte ghosts⁶² and intact myelin membranes.⁷ CP MAS was used to determine the headgroup and hydrocarbon packing in

hydrated and dry phospholipids.^{31–33,63} Subsequently, the interfacial conformation of the glycerol backbone of lipids in phospholipid bilayers⁶⁴ was characterized using specifically labeled lipids and ¹³C MAS NMR. Two-dimensional ¹H–¹³C heteronuclear chemical shift⁶⁵ and NOESY spectra⁶⁶ of phospholipid–water dispersions have been recorded using solid state MAS techniques. Recently, ¹³C MAS NMR has been demonstrated as a powerful tool for examining structure and motions of cholesterol⁶⁷ and cholesteryl esters⁶⁸ in crystalline and liquid crystalline phases and the molecular organization in phospholipid-triglyceride aqueous dispersions.⁶⁹ Further, MAS ¹³C NMR *T*₁ relaxation studies were used to determine the location and effects of α -tocopherol and ubiquinone in unsonicated model membranes.⁷⁰ The application of MAS techniques for the determination of the structure of integral membrane proteins will be discussed in the following section.

3 MEMBRANE PROTEIN STRUCTURE

Biological membranes greatly restrict the motion of integral proteins, and consequently solid state NMR is more suitable for structural studies of membrane proteins than solution methods. Nevertheless, conventional high-resolution NMR spectra of membrane proteins have been obtained by replacing the membrane lipids with detergents which form micelles in solution, e.g. ¹H spectra of gramicidin A in micelles.⁷¹ Carbon-13 NMR studies have been performed on ¹³C-enriched retinals embedded in bacteriorhodopsin solubilized in detergent.⁷² More recently, ¹³C spectra have provided both structural and dynamic information from hydrophobic oligopeptides,⁷³ the major coat protein of bacteriophage M13,^{74,75} bacteriorhodopsin,^{76,77} and cytochrome *c* oxidase⁷⁸ in micellar systems. Phospholipid vesicles were used to study the mobility of incorporated ¹³C-enriched glycophorin A, a transmembrane glycoprotein,⁷⁹ using conventional solution state NMR methods. From relaxation measurements and accessibility to paramagnetic NMR probes, the ion channel gramicidin A was demonstrated to be an N-terminal to N-terminal helical dimer in phospholipid vesicles using ¹³C-enriched gramicidin A.⁸⁰ However, vesicle systems have limited use for solution studies of membrane proteins as the small, unilamellar vesicles tend to aggregate, and solid state techniques are required.

For the study of membrane proteins, severe broadening as a result of incomplete averaging of dipolar interactions can be overcome by applying high-resolution solid state NMR techniques. The magnetically dilute spin- $\frac{1}{2}$ nuclei such as ¹³C have had the most far-reaching application since the CSA is the dominant spin interaction in the NMR spectrum. The CSA can, in principle, be directly related to molecular structure if the axis system of the chemical shift tensor has been determined relative to a molecular fixed axis system. This directional information conveyed by the CSA is lost in solution studies that only retain the isotropic component of the shift tensor. Magic angle spinning has been widely used for resolving isotropic and anisotropic chemical shifts. A common approach for determination of membrane protein structure has been selective isotopic enrichment at specific sites and the use of MAS combined with CP and proton decoupling.

Alternative approaches, including oriented samples, have been applied to measure dipolar couplings and CSAs and these have been related to molecular structures. Hydrated dispersions of phosphatidylcholine incorporating specifically ¹³C-labeled gramicidin A have been aligned on glass coverslips to improve spectral resolution. The experimental CSA of the ¹³C carbonyl resonance of the labeled peptide was compared with the values calculated for various proposed models.⁸¹ The membrane ion channel form of gramicidin A was consistent with a $\beta^{6.3}$ single helix. An accurate knowledge of the principal values and direction cosines of the CSA tensor is crucial for the interpretation of the oriented NMR spectra. These values may be determined from single crystal studies or from powder samples if the nucleus under investigation is dipole-coupled to a nearby nucleus.⁸²

Solid state ¹³C NMR spectroscopy is capable of determining the structure of membrane polypeptides to high resolution, including both backbone⁸³ and side-chain groups. The orientation of the tryptophan side chains was determined using gramicidin A, ¹³C labeled at the indole C-2 of tryptophan, and macroscopically aligned in phospholipid dispersions.⁸⁴ Carbon-13 NMR was further utilized to demonstrate the Na⁺ binding site in specifically ¹³C-labeled gramicidin A channels incorporated within model membrane systems.^{85–87} Two-dimensional REDOR of ¹³C–¹⁵N-labeled gramicidin A in multilamellar dispersions⁸⁸ further defined the ion channel form to be the $\beta^{6.3}$ -helix.

The dynamics and aggregation of alamethicin, another peptide ion channel, was determined using ¹³C NMR of spin-labeled peptides and phospholipid vesicles.⁸⁹ The results indicated that the ion-conductive aggregate represents only a minor fraction of the total membrane-bound peptide. Natural abundance *T*₁ measurements and ¹³C–¹H NOEs of alamethicin in methanol suggested that the peptide is a rigid helix in the membrane.⁹⁰ Rotational resonance measurements of a ¹³C-labeled undecapeptide, analogous to the N-terminus of alamethicin, within membrane bilayers, have shown that the peptide maintains a helical structure.⁹¹ These studies have demonstrated that ¹³C–¹³C distances of up to 0.68 nm can be measured with an accuracy of up to 0.05 nm using rotational resonance techniques.

Melittin, a constituent of bee venom, is one of the most extensively studied membrane peptides. Carbon-13 relaxation measurements of the motion of fatty acyl chains in multibilayers of chloroplast membrane lipids and melittin,⁹² were consistent with the melittin penetrating deep into the bilayer. However, ¹³C relaxation measurements of lipids in melittin-containing vesicles⁹³ were interpreted as evidence for a surface rather than transmembrane orientation of the melittin helix. Solid state ¹³C CP NMR studies of melittin in aligned lipid multilayers indicated that at higher concentrations of the peptide melittin inserted within the lipid bilayer.⁹⁴ The dynamics of tryptophan side chains and the peptide backbone has been studied using selectively ¹³C-enriched melittin in lipid vesicles and micelles.⁹⁵ The data were found to be consistent with a transbilayer orientation of the N-terminal α -helical segment.

Information about the secondary structure of virus fd coat proteins oriented by the magnetic field has been obtained using doubly labeled ¹³C–¹⁵N peptides.^{96,97} The protein has been studied both as an intrinsic membrane protein reconstituted into phospholipids, and as the native form found in the

virion. Spectra obtained from ^{13}C carbonyl-labeled Pf1 coat protein display motional averaging consistent with the protein being predominantly α -helical, with the helix axis aligned approximately parallel to the phage filament.⁹⁸ The C-terminal residues were found to be rigid when the protein formed the outer coat of the virus, and highly mobile when the protein was in a lipid bilayer.

A larger membrane protein, [1- ^{13}C]leucine bacteriorhodopsin, incorporated within a phospholipid bilayer was shown to undergo rotational diffusion about an axis parallel to the bilayer normal, resulting in a narrowing of the peptide carbonyl lineshapes.⁹⁹ The dynamic structure of the backbone of bacteriorhodopsin in purple membranes was deduced from ^{13}C spectra obtained from samples using biosynthetically incorporated ^{13}C -labeled amino acids.¹⁰⁰

Solid state NMR studies of ^{13}C -labeled retinal, the chromophore in bacteriorhodopsin and rhodopsin, have been carried out in both dry and hydrated samples.^{101–103} Dark-adapted bacteriorhodopsin was shown to contain a mixture of retinal isomers from the ^{13}C peak splitting.¹⁰⁴ From the isotropic chemical shift and principal values of the chemical shift tensor of the ^{13}C -5 label, it was demonstrated that retinal is in a 6-*s-cis* conformation in rhodopsin but in the 6-*s-trans* form in bacteriorhodopsin.^{103,104}

Rotational resonance NMR was used to measure the distance between the C-8 and C-18 carbons of retinals within bacteriorhodopsin,¹⁰⁵ an integral membrane protein. Further, solid state ^{13}C MAS NMR has been used to investigate light-induced and temperature-dependent changes between 215 and 260 K, in detergent-solubilized photosynthetic reaction centers of *Rhodobacter sphaeroides*,¹⁰⁶ selectively enriched with [4- ^{13}C]tyrosine. Similarly, [4- ^{13}C]aspartic acid resonances were used to study light and dark adaption of bacteriorhodopsin.¹⁰⁷ By ^{13}C -labeling both the retinal chromophore and the lysine side chain of the protein, rotational resonance NMR was used to measure the active site distance in a membrane protein.¹⁰⁸ An important aspect of these studies has been the development of ^{13}C NMR solid state techniques for investigating the tertiary structure of membrane proteins within biological systems.

4 CONCLUSIONS

The above examples have illustrated the value of ^{13}C NMR spectroscopy as a tool for the study of membrane systems. Membranes are complicated structures and in order to elucidate their organization, it has been necessary to examine model systems such as lipids and lipid-protein complexes. With the developments in pulse methods and selective enrichment, ^{13}C NMR has enabled the study of the motion and orientation of particular membrane sites, and to relate these results to the structure and function of biological membranes.

1 INTRODUCTION

Biological systems are rich in hydrogen nuclei, and the NMR of hydrogen has in many cases yielded beautifully detailed descriptions of molecular structure and dynamics in biology. The abundant isotope of hydrogen, ^1H , while possessing a large magnetic moment and, therefore, a significant sensitivity advantage, suffers from the lack of a quadrupolar moment, being a spin- $\frac{1}{2}$ nucleus. Deuterium, with a spin of 1, has a conveniently sized quadrupolar moment, which makes this nucleus a sensitive probe of its environment within the molecule and of the reorientational motions of the molecule in a magnetic field. This more than compensates for what is lost in intrinsic signal sensitivity relative to ^1H . In addition, for partially ordered systems such as solids, liquid crystals, and membranes, the high natural abundance and strong magnetic dipole–dipole interactions among ^1H nuclei generally result in a broad, featureless, NMR spectrum whose potentially rich information content has been lost. The quadrupolar interaction between the ^2H quadrupolar moment and the electric field gradient tensor at the nucleus dominates its NMR spectrum, dipole–dipole interactions even with surrounding ^1H nuclei often being negligible. Thus, by selective isotopic labeling with deuterium, one can probe local structural and dynamic details at virtually any site within a biological system.

2 MEMBRANES: DYNAMIC ANISOTROPY AND COMPOSITIONAL HETEROGENEITY

The membranes of living cells, although tremendously varied, show a common basic structure, that of the lipid bilayer. The amphiphilic character of lipid molecules typically results in the presence of excess water, with the formation of thin (4–6 nm) bimolecular films, which serve not only to encapsulate individual cells but also to compartmentalize the interior of the cell (in the case of eukaryotes). The lipid

polar headgroups form the two surfaces of the bilayer at the lipid/water interface, while the lipid hydrocarbon chains lie at the interior of the bilayer. The physical properties of the membrane are strongly dependent on its molecular composition. Biological membranes may contain hundreds of chemically distinct lipid molecules, differing in headgroup composition, some of the different classes being phospholipids, glycolipids, sphingolipids, etc. or having different chain compositions, differing in chain length, degree of unsaturation, etc. In addition, the membranes of higher organisms are often rich in sterols, cholesterol in particular for mammalian cells. In fact, the cholesterol content can be as high as 60 mol% of the total lipid fraction of the membrane (where sterols and lipids are considered to form the lipid fraction). Into this already heterogeneous lipid matrix are inserted a wide variety of different protein molecules. Again there are perhaps hundreds of distinct proteins each with specific biochemical or structural functions to perform within the membrane. The proteins' functions are determined by the type of membrane, e.g., photosynthesis in the case of the chloroplast thylakoid membranes, oxidative phosphorylation in the mitochondrial inner membrane, gated ion channels in excitable membranes, absorption of light by rhodopsin in the retinal rod outer segment disk membranes. In addition, both glycolipids and glycoproteins determine cell type specificity and are involved in cell–cell communication and recognition in general. Innumerable biochemical processes occur at the membrane surface and even those occurring within the cell cytoplasm or within the various organelles are mediated or regulated by processes occurring within the membrane. The realization of the fundamental role of membranes in the performance and regulation of cellular biochemical processes has led to widespread interest in the biology, chemistry, and physics of natural and model membrane systems.

Under physiological conditions most natural membranes are in a 'fluid' state, characterized by rapid molecular reorientation and diffusion of both lipid and protein molecules. Due to the bilayer symmetry of the membrane these motions are anisotropic, e.g., lateral diffusion within the plane of the membrane is generally rapid, and the 'flip-flop' of a molecule from one side of the bilayer to the other is very slow. Individual molecular reorientations are also anisotropic: axial diffusion of lipids or proteins about an axis roughly aligned along the bilayer normal is often fast and relatively unrestricted while reorientation of the molecule in the directions perpendicular to the bilayer normal is highly restricted. The fluid membrane is an anisotropic fluid or liquid crystal: the molecules possess orientational order in one dimension but are positionally disordered in two dimensions.

The two characteristics of biological membranes that dominate their physical properties are their compositional heterogeneity and their dynamic anisotropy. Because of the molecular heterogeneity and the highly fluid nature of the membrane, there is an almost total lack of positional order within the bilayer plane. There are some notable exceptions, such as bacteriorhodopsin in the purple membranes of *Halobacterium halobium*,¹ where the proteins can form large two-dimensionally ordered patches. In these cases, diffraction techniques can be used to study the structure of the protein. However, for the typical membrane, diffraction experiments can at best provide only qualitative information on molecular structure, although they can provide a great deal of information

on the phase behavior and long-range structure of many model membrane systems.

The anisotropy in the molecular reorientations within the membrane presents both a challenge and an opportunity for NMR spectroscopy. Because these systems are partially ordered (which leads to the anisotropy in the motions), the second rank tensor spin interactions, such as the magnetic dipole–dipole interaction, the anisotropic part of the chemical shift, and the quadrupolar interaction, dominate the NMR spectrum. This results in broad lines, similar to those observed in solids, that often completely obscure the fine detail potentially available from the isotropic parts of the chemical shifts and the J couplings that have been so valuable in structure determinations of molecules in isotropic solutions. In the case of abundant like nuclei interacting via strong dipole–dipole interactions, as is the case with ^1H nuclei of lipids or proteins, the normal spectrum of a fluid membrane will be a largely featureless bump with little or no structural detail. However, the second rank tensor interactions are exquisitely sensitive to the orientation of the molecular segment relative to any local symmetry axis for the motions (typically the bilayer normal or a long molecular diffusion axis), and to the extent of motional averaging perpendicular to that axis. By specific isotopic labeling, and by removing if necessary any strong dipolar coupling to surrounding protons (by proton decoupling), it is possible to use the second rank tensor interactions to probe the local molecular structure, orientation, order, and dynamics. Thus, measurement of the residual part of the quadrupolar interaction for a ^2H nucleus in a $\text{C}-^2\text{H}$ bond can yield valuable structural and dynamic details at the labeled position.

3 ^2H NMR: PROBING ORIENTATIONAL ORDER, STRUCTURE, AND DYNAMICS

It is the orientation dependence of the electric quadrupolar interaction that permits the study of molecular orientational order, structure, and dynamics by ^2H NMR. In the large magnetic fields commonly used in NMR laboratories (i.e., for $B_0 > 1\text{ T}$) the ^2H quadrupolar interaction is small relative to the Zeeman Hamiltonian. In particular, since the gyromagnetic ratio of deuterium is $\gamma = 6.536\text{ MHz T}^{-1}$, at a field of 8.5 T the Larmor precession frequency, ν_0 , is 55.26 MHz , whereas the deuterium quadrupolar coupling constant for a ^2H nucleus in a typical $\text{C}-^2\text{H}$ bond is only 167 kHz . Thus, in the theoretical description of ^2H NMR we may treat the quadrupolar Hamiltonian as a small perturbation on the Zeeman Hamiltonian. Of equal importance is the fact that the nuclear dipole–dipole interactions experienced by a ^2H nucleus are small compared with the quadrupolar interaction, being of the order of a few kHz for $^1\text{H}-^2\text{H}$ dipolar coupling, and correspondingly weaker for other types of neighboring nuclei (since the ^1H gyromagnetic ratio is second only to that of ^3H). Finally, the range of ^2H chemical shifts is quite small, like that for ^1H , being only about $15\text{--}20\text{ ppm}$ (about 1 kHz at 8.5 T). For ^2H , the quadrupolar Hamiltonian dominates its NMR spectrum and its relaxation behavior, all other contributions being relatively small. Under certain circumstances the dipolar coupling with surrounding ^1H nuclei can significantly broaden the ^2H spectrum and

shorten the transverse relaxation time. In these cases, ^1H decoupling can be used either to eliminate or to quantitate and measure this effect. For these reasons, the theoretical description of ^2H spectroscopy and relaxation are particularly straightforward. The detailed theoretical analysis has been presented in a number of recent review articles^{2–7} and will not be repeated here. However, a brief summary of the principles is appropriate.

The quadrupolar Hamiltonian in the electric field gradient's principal axis system, which is fixed within the molecular segment, can be written

$$\hat{H}_Q = \frac{eQ}{2} \sum_{m=-2}^2 (-1)^m \hat{T}_{2m} F_{2-m}^P \quad (1)$$

where the electric field gradient (EFG) tensor in its principal axis system is defined by

$$\begin{aligned} F_{2,0}^P &= \sqrt{\frac{3}{2}} eq \\ F_{2,\pm 1}^P &= 0 \\ F_{2,\pm 2}^P &= \frac{1}{2} eq \eta \end{aligned} \quad (2)$$

and the second-rank spherical tensors for the spin variables are

$$\begin{aligned} \hat{T}_{2,0} &= \sqrt{\frac{1}{6}} [3\hat{I}_z^2 - I(I+1)] \\ \hat{T}_{2,\pm 1} &= \mp \frac{1}{2} (\hat{I}_z \hat{I}_{\pm} + \hat{I}_{\pm} \hat{I}_z) \\ \hat{T}_{2,\pm 2} &= \frac{1}{2} \hat{I}_{\pm}^2 \end{aligned} \quad (3)$$

If a transformation from the EFG tensor principal axis system to the laboratory fixed coordinate system is defined by the Euler angles (α, β, γ) , then the quadrupolar Hamiltonian is written

$$\begin{aligned} \hat{H}_Q &= \frac{e^2 q Q}{8} [3\hat{I}_z^2 - I(I+1)] (3 \cos^2 \beta - 1) \\ &\quad + \eta \sin^2 \beta \cos 2\alpha \end{aligned} \quad (4)$$

(The angle γ does not appear because the direction of the static laboratory field, $\mathbf{B}_0$, defines the z axis only and we are free to choose γ to be zero.) For ^2H , which has spin $I = 1$, this leads to the orientation-dependent quadrupolar splitting

$$\omega_Q = \frac{3e^2 q Q}{4\hbar} [(3 \cos^2 \beta - 1) + \eta \sin^2 \beta \cos 2\alpha] \quad (5)$$

If the structural or dynamic symmetry of the system suggests an intermediate coordinate frame, we can interpose a second transformation via a second set of Euler angles $(\alpha', \beta', \gamma')$. In the case of the fluid phase of membranes, this intermediate coordinate system is defined by the local bilayer normal, which is an axis of symmetry for the motions. Because of this

symmetry, the Euler angle α may also be taken to be zero, and we obtain the expression for the average quadrupolar splitting

$$\begin{aligned}\langle\omega_Q\rangle &= \frac{e^2qQ}{4\hbar}(3\cos^2\beta' - 1)\frac{1}{2}\langle(3\cos^2\beta - 1) \\ &\quad + \eta\sin^2\beta\cos 2\alpha\rangle \\ &= \frac{e^2qQ}{4\hbar}(3\cos^2\beta' - 1)\frac{1}{2}[S_{zz} + \frac{1}{3}\eta(S_{xx} - S_{yy})] \quad (6)\end{aligned}$$

where β' is the angle between the bilayer normal and the static magnetic field and where the angular brackets are averages over the molecular motions occurring on the ^2H NMR timescale (which is at least loosely defined by the inverse of the residual quadrupolar splitting). This expression also introduces the ‘order parameter’ tensor, $\mathbf{S}$, at the labeled position.

Rapid molecular reorientation decreases the sizes of the quadrupolar splittings from their static values. If the reorientation is isotropic, the averages in equation (6) are zero and the spectrum collapses to an ‘isotropic’ singlet. The magnitude of the residual quadrupolar splitting depends, in this fashion, on the orientational averaging present. In the case of partially ordered, anisotropic systems, and in particular for membranes, it depends also on the average orientation of the efg tensor with respect to the local bilayer normal. Since for $\text{C}-^2\text{H}$ bonds the efg tensor at the ^2H nucleus is nearly axially symmetric (η is generally in the range 0.01–0.03), and the principal, or z axis of the efg system lies along the $\text{C}-^2\text{H}$ bond, the quadrupolar splitting can be used to determine the orientation of the bond relative to the bilayer normal (there can remain some ambiguity due to the dependence on $\cos^2\beta$, which leads to two solutions with the same splitting for $35^\circ \leq \beta \leq 90^\circ$) (except at the magic angle where the splitting is 0).

Molecular reorientations also affect the ‘relaxation’ of the spin system to its equilibrium state after the perturbation due to the rf pulses in the NMR experiment. In fact, for ^2H , the fluctuations of the quadrupolar Hamiltonian dominate these relaxation processes. The time-dependent quadrupolar Hamiltonian, which can be divided into its static and fluctuating parts,

$$\hat{\mathcal{H}}_Q(t) = \langle\hat{\mathcal{H}}_Q\rangle + [\hat{\mathcal{H}}_Q(t) - \langle\hat{\mathcal{H}}_Q\rangle] \quad (7)$$

describes the recovery of all of the elements of the density operator to their equilibrium values. For ^2H , the density operator may be represented by a 3×3 matrix or it may be expanded in terms of a set of nine independent operators, $\hat{Q}_q$, such that

$$\rho(t) = \sum_q c_q(t) \hat{Q}_q \quad (8)$$

The solution of the Liouville equation gives the time evolution of the density operator (and of the spin system). For ^2H this leads to a set of eight coupled first-order differential equations (the ninth involves the identity operator), which can often be solved analytically. In the Redfield approximation, we can use these equations to define the spin-1 relaxation times: T_{1Z} , for the decay of Zeeman polarization (the spin–lattice relaxation time); T_{1Q} , for the decay of quadrupolar polarization; T_{2e} , the decay of transverse magnetization; and T_{DQ} , the decay

of double quantum coherence.^{2,6,8} The decay of the fifth coherence, which is zero quantum coherence, is related to the decay of the transverse magnetization.

Careful experimental measurement of the residual quadrupolar splitting and of the relevant relaxation times can lead to an accurate description of local molecular orientation, order, and dynamics.

4 BEFORE THE QUADRUPOLEAR ECHO

In 1969 Charvolin and Rigny⁹ published their work on the continuous wave broadband NMR study of ^2H in mixtures of $^2\text{H}_2\text{O}$ and potassium laurate. Among the phases formed by this soap/water lyotropic liquid crystalline system is a lamellar phase which has served as a simple and useful model for the biological membrane. Two years later, Oldfield et al.,¹⁰ applied the same technique to a phospholipid model membrane system formed from chain perdeuterated dimyristoylphosphatidylcholine (DMPC) and $^1\text{H}_2\text{O}$. This study showed the influence of the gel-to-liquid-crystalline phase transition and the effect of cholesterol on lipid hydrocarbon chain mobility, and demonstrated the potential of ^2H NMR for the study of molecular order and dynamics in membrane systems. In 1972 the same authors¹¹ published the results of the first ^2H NMR experiments on biological membranes, studying the membranes extracted from *Acholeplasma laidlawii* grown in media supplemented with perdeuterated lauric and palmitic acids. The introduction of pulsed NMR and the Fourier transform did not have a large effect on the quality of the ^2H spectra obtained from membrane systems nor on the sensitivity. Nonetheless, the field developed rapidly from this point. Charvolin et al.¹² published their study of chain-perdeuterated potassium laurate in 1973 and, shortly afterwards, Seelig and Seelig¹³ published the results of their experiments on a series of specifically deuterated dipalmitoylphosphatidylcholine (DPPC)/water samples. These experiments demonstrated the existence of a ‘flexibility gradient’ across the bilayer, the chain positions near the lipid/water interface being significantly more ordered than those near the center of the bilayer. Stockton et al.¹⁴ studied the order and dynamics, using both T_{1Z} and T_2 measurements of deuterium labeled phospholipid and fatty acid probes in egg phosphatidylcholine bilayers, using both sonicated vesicles and multilamellar dispersions. By the end of 1975 numerous studies had been published on the orientational order and dynamics of model membrane systems, demonstrating among other things, the inequivalence of the two hydrocarbon chains of phospholipids,¹⁵ the conformation and dynamics of the phospholipid headgroup,¹⁶ and the differences between the description of chain order given by electron paramagnetic resonance (EPR) spin labels and ^2H NMR.¹⁷ In addition, these early studies introduced the use of oriented samples^{12,14,18} and demonstrated that the bilayer normal was an axis of symmetry for the motions.

5 TECHNICAL ISSUES AND DEVELOPMENTS

The major experimental difficulty encountered in these early experiments was the combination of the finite receiver dead time and the very broad lines, with the subsequent rapid decay

Figure 1 Deuterium NMR spectra of chain-perdeuterated DMPC/water dispersion in (a) the fluid or liquid crystalline phase, and (b) the gel phase, at the temperatures shown. Spectrometer frequency was 55.26 MHz

of the magnetization following a 90° pulse. The FID envelope of a fluid phase powder sample with a width of about 30 kHz will decay to $1e^{-1}$ of its initial value within 20 or 30 μ s and the receiver dead time at the low frequencies then in use (typically 8–15 MHz) is about the same. This results in a serious distortion of the spectrum which cannot be corrected by phase adjustments.¹⁹ The situation is even more serious for a sample in the gel phase where the quadrupolar splittings from C– 2 H bonds can be as large as 126 kHz. Thus, the early studies were restricted to membranes and lyotropic liquid crystals in their fluid phases.

The introduction of the quadrupolar echo¹⁹ solved this problem, making it possible to obtain high-quality spectra displaying the true powder pattern lineshape even for lipids in the gel phase²⁰ (Figure 1). Since the sign of the quadrupolar echo depends on the phase of the first pulse but not on the second, we were able to eliminate ringing from the probe by alternating the phase of the first pulse between 0 and 180° . This was later extended to more complex phase cycling schemes.^{3,5} The high fidelity of the lineshapes led to the use of the moments of the spectra for the quantitative description of hydrocarbon chain order. In the fluid phase, the first moment (calculated from the upper half of the symmetrical 2 H spectrum) is proportional to the average quadrupolar splitting.^{3,20} The liquid-crystalline-to-gel phase transition, which occurs as the sample is cooled, results in a sudden dramatic increase in the quadrupolar splittings, which is reflected in the moments of the spectrum. This led to the use of 2 H NMR ‘calorimetry’ for the study of phase transitions and phase equilibria in lipid/lipid, lipid/sterol, lipid/peptide, and lipid/protein mixtures.^{5,6}

The broad lines observed in the gel phase presented two additional spectroscopic challenges. Firstly, the large

quadrupolar splittings, ω_Q , were comparable to the amplitude, ω_1 , of the rf pulses, leading to substantial distortion of the spectrum. The extent of this distortion can be calculated analytically,²¹ and was found to vary strongly with ω_1/ω_Q and with the length of the $\pi/2$ pulse. For undistorted spectra with splittings of 126 kHz, it would be necessary to use $\pi/2$ pulses of 1 μ s or less to obtain essentially undistorted spectra. However, by using shorter pulses, which may not correspond to a full $\pi/2$ rotation, it is possible to sacrifice signal-to-noise ratio for improved spectral fidelity. The second challenge arose because of the decay of transverse magnetization during the time between pulses. To avoid the preamp dead times of 20–30 μ s one needs to use an echo delay, τ , which is at least of the same magnitude. If the echo decay time, T_{2e} , is comparable, and is a function of orientation (within the powder sample), then the lineshape changes with τ . However, this presents a problem since it is not possible to obtain directly the true lineshape corresponding to $\tau = 0$, but it does, however, provide a method of studying the slow molecular motions that are responsible for the rapid orientation-dependent transverse relaxation in these systems.²²

The spectra of chain-perdeuterated lipids in the liquid crystalline phase, such as that shown in Figure 1, can provide a description of the distribution of quadrupolar splittings. These spectra consist of a superposition of overlapping powder patterns and the sharp discontinuities corresponding to the 90° orientation allows the measurement of the C– 2 H bond ‘order parameters’, S_{C-D} . If the molecules undergo rapid axially symmetric reorientation, the powder pattern lineshapes can be ‘de-Paked’ to yield the spectrum that would have been obtained from an oriented sample.²³ This allows one to follow more easily the changes in chain order profile that occur as temperature, pressure, sample composition, etc. are varied.

If the spectra are of sufficiently high fidelity and the signal-to-noise ratio is sufficient, it is possible to study the phase behavior of mixed systems using the technique of spectral subtraction.^{4,5,24,25} Since a thermodynamic mixture in a two phase coexistence region will consist of domains of different composition, it will be possible to quantitate the partitioning of the system between the different domains provided that the 2 H-labeled molecules do not diffuse rapidly between the two types of domains during the spectroscopic timescale, and provided that there is a significant, observable difference between the spectra characteristic of labeled molecules in the two domains. In the case of gel/fluid coexistence regions, the 2 H NMR spectra of lipids in fluid and gel phase are dramatically different (see Figure 1), and it is often straightforward to identify two components in the spectra. In this case, by performing pairwise spectral subtractions, one can use the lever rule to determine the end point concentrations of the two phase region.

Perhaps the major remaining experimental limitation to 2 H NMR is the low signal-to-noise ratio caused by the small nuclear gyromagnetic ratio of deuterium. Since the signal-to-noise ratio scales as $B_0^{3/2}$, the large superconducting magnets that have become available during the past 20 years have had a tremendous impact on the application of 2 H NMR to biological systems. Further increases in magnetic field strength will be especially valuable for 2 H NMR of membranes since the spin–lattice relaxation times are short even at high fields and the chemical shift dispersion is very small compared with the quadrupolar splittings observed in membranes. Already it

Figure 2 Deuterium NMR spectrum of a single 'sandwich' of approximately 3 mg of chain-perdeuterated dilauroylphosphatidylcholine/water between two thin glass plates with an area of about 1 cm². Spectrometer frequency was 55.26 MHz, temperature was 35 °C, and the spectrum was the result of 3000 acquisitions at a repetition time of 0.5 s. The glass plates were oriented with their normal parallel to the external magnetic field

is possible to obtain good spectra from as little as 1 μ mol of deuterium, making it possible in some cases to study even natural abundance samples. Finally, techniques for making oriented samples with lipids or mixtures of lipids and other molecules have been perfected, and one can obtain excellent spectra from even a single 'sandwich' of lipid between glass plates, as illustrated by Figure 2.

6 APPLICATIONS

Many of the innovations in the technique of ²H NMR have already been described. A review of all of its applications to membranes would be beyond the scope of this short article. However, it is important to discuss a few selected applications, some of historical significance and some very recent, to show the current state of the field. These have been grouped by system, beginning with simple lipid mixtures and ending with natural membranes.

6.1 Lipid/Water, Lipid/Sterol, and Lipid/Lipid Mixtures

The earliest applications of ²H NMR to model membranes were studies of water: ²H₂O. Perhaps surprisingly there is still a lot to be learned about the order and dynamics of water in membrane systems. Hence it is still a very active area of research.^{26,27} Of particular interest are the effects at low levels of hydration where the role of water in determining lipid headgroup conformation and the overall structure of the phase becomes evident.

The influence of hydrostatic pressure on molecular order and the phase behavior of lipid/water systems has recently been investigated by ²H NMR.²⁸ Lipid/lipid mixtures also exhibit some very interesting phase behavior. A recent study using ²H NMR difference spectroscopy²⁹ has determined the phase diagram of mixtures of DMPC/DSPC, where the difference

between chain lengths of the two lipids leads to very nonideal mixing.

One of the most important components of biological membranes is cholesterol, which can make up more than 50 mol% of the lipid content of a membrane. ²H NMR difference spectroscopy, combined with other techniques, has helped to elucidate the phase equilibria of DPPC/cholesterol mixtures²⁵ and to describe the effects of cholesterol on lipid order and dynamics and on the physical properties of the bilayer.^{25,30} At high cholesterol concentrations, the system enters a new 'liquid-ordered', or ' β ', phase, which seems to be the phase characteristic of natural membranes that are rich in cholesterol, such as the cytoplasmic membranes of mammalian cells.

6.2 Peptide/Lipid Mixtures

²H NMR difference spectroscopy was originally applied to mixtures of a synthetic amphiphilic bilayer spanning peptide in chain-perdeuterated DPPC³¹ to determine the phase behavior. The influence of this peptide on lipid chain order and dynamics has been studied extensively by ²H NMR.³² A similar system, formed from mixtures of the natural channel-forming peptide gramicidin A, has also been investigated by ²H NMR. These studies examined the effect of the peptide on lipid order and dynamics and phase equilibria,³³ and on the structure and dynamics of the peptide itself.^{34–36} By exchange labeling the peptide it is possible to study the backbone structure and dynamics through the ²H spectra of the amides. Figure 3 shows a spectrum of exchange-labeled gramicidin A in bilayers of dilauroylphosphatidylcholine (DLPC) oriented between glass plates. The sample contained about 20 mg of exchange-labeled gramicidin and 150 mg of lipid, and the plates were oriented with their normal perpendicular to the static magnetic field. Relaxation measurements, both T_{1Z} and T_{1Q} , were made as a function of the orientation of the glass plates (bilayer normal)

Figure 3 Deuterium NMR spectrum of exchange-deuterated gramicidin D (from *Bacillus brevis*) in DLPC/water oriented between glass plates. Each of the 15 amide positions and the indole positions of the four tryptophan residues are labeled. The spectrum is the result of about 120 000 acquisitions using a repetition time of 0.9 s at a temperature of 65 °C. The glass plates are oriented with their normal perpendicular to the applied magnetic field

with respect to the field. These results led to a model for the reorientation of the peptide within the fluid bilayer wherein gramicidin diffuses axially with a correlation time of about 7 ns and the diffusion axis diffuses perpendicular to the bilayer normal, in an orienting potential, with a correlation time of about 6 μ s.³⁶

6.3 Protein/Lipid Reconstitutions

The question of the role of lipid diversity in membrane function led to the study of reconstituted protein/lipid mixtures where carefully prepared and purified membrane proteins are reinserted into lipid bilayers of defined composition, often consisting of a single lipid type. The interaction between protein and lipid in these reconstituted membranes had been studied by many techniques, most notably EPR. The EPR results suggested the existence of an 'annulus' of ordered lipid surrounding a protein, and many experiments were designed to study the specificity of this protein/lipid interaction. ²H NMR of labeled lipids was soon applied to these same systems,³⁷ and it was quickly discovered that these 'boundary' lipids did not reside on the protein surface for long periods of time, i.e., that they readily exchanged with 'bulk' lipids. The different views offered by EPR and NMR were related to the very different spectroscopic timescales of the two techniques.^{38–40} An important realization arising from this work was that Nature designs membrane proteins and the lipid composition of the natural membrane to closely match each other so that the incorporation of large quantities of protein does not change dramatically the properties of the bilayer, and so that the properties of the lipid do not adversely affect the function of the protein.

²H NMR studies of protein/lipid interactions and of the phase behavior of protein/lipid mixtures have continued and are qualitatively in agreement with work on the simpler peptide/lipid model systems discussed earlier.^{41–43} One of the more interesting, unresolved questions is whether or not the protein/lipid or peptide/lipid mixtures at physiological concentrations are near a critical mixing point.

6.4 Natural Membranes

The ²H NMR spectra of the membranes of *A. laidlawii* grown on specifically deuterated palmitic acids⁴⁴ demonstrated that natural biological membranes exhibited the same hydrocarbon chain flexibility gradient as had been observed in fluid-lamellar-phase phospholipid/water dispersions. The incorporation of cholesterol, normally absent in *A. laidlawii* membranes, had a profound influence on the lipid order and suppressed the chain melting transition,^{45,46} as was later observed in human erythrocyte ghosts into which either perdeuterated palmitic acid⁴⁷ or DPPC⁴⁸ had been incorporated. These observations are in agreement with the results of studies of DPPC/cholesterol mixtures^{25,30} and suggest that the ' β ', or 'liquid ordered' phase is the natural state of the membranes of cells rich in cholesterol. Similar results have been recently reported in a related bacterial system, *Mycoplasma capricolum*.⁴⁹

Comparisons of the inner and outer membranes of *Escherichia coli* grown on deuterated palmitic acids^{50,51} were

made as a function of temperature in order to investigate the influences of membrane composition on lipid order and dynamics. The differences observed were subtle even though the compositions of the inner and outer membrane were widely different, the most significant difference being the predominance of lipopolysaccharide on the outer leaflet of the outer membrane. The influences of membrane protein on lipid order and conformation were equally subtle, resulting only in modest changes in chain order and small decreases in spin-lattice relaxation time, in agreement with work on reconstituted systems.

These studies, and others, demonstrated that lipid/water dispersions were excellent models of natural membranes, exhibiting the same hydrocarbon chain ordering, the same gel, fluid, and ' β ' phases, the same polar headgroup organization,⁵² and the same sensitivity to cholesterol.

7 CONCLUSION

Over the past 25 years the application of ²H NMR to membrane systems has changed and expanded dramatically. Its capabilities and potential are greater than ever, and the continued development of more powerful magnets will open up new possibilities. At the present time it is just becoming possible to study the backbone dynamics of membrane-bound peptides and proteins. Improvements in signal-to-noise ratio will make these studies routine in a few years time.

1 INTRODUCTION

Phosphorus-31 NMR is a powerful, nonperturbing probe of membrane structure and dynamics, both for model and for biological membranes. Mammalian cell membranes, and most other cellular membranes, contain phospholipids as a major component. Phospholipids each have a phosphate group (or in some cases, more than one) so that the 100% natural abundance of the ³¹P isotope (and its relatively high sensitivity) can be exploited to explore the properties of phospholipids in membranes from ³¹P NMR, and, from that, extract information about the membranes themselves.

Phosphorus-31 NMR of membranes has provided considerable information on membrane structure and dynamics since the first ³¹P NMR spectra of membranes were published.¹⁻⁴ The following will provide insight into the system, the lipid bilayer and biological membrane, and will follow with an analysis of the usage of ³¹P NMR for problem solving. Specific problems will be used as examples of how this approach has been used. The reader is referred to the literature for more detail. Reviews (from which much of the older information in the following discussion is derived) with more extensive literature citations are available.⁵⁻⁷

2 ³¹P NMR IN THE ASYMMETRIC ENVIRONMENT OF MODEL AND BIOLOGICAL MEMBRANES

2.1 Membrane Structure

Much of the function and structure of living cells is determined by the membranes of those cells.⁸ As an example, consider the plasma membrane of mammalian cells, which determines the outer boundary of those cells, controls the permeability of solutes into and out of the cell, and pumps essential nutrients in and out of the cell. The plasma membrane

contains the receptors that transduce the signals from the outer environment (outside the cell) to the interior of the cell. The plasma membrane anchors the glycoproteins that play roles in cell-cell recognition and the immune response. These and other functions echo throughout the architecture of living cells, with an incredible array of cell membranes supporting basic cell function, cell growth, and cell differentiation.

An understanding of cell membrane structure and function can be gained through a study of the structural components of the membranes. The two most important classes of membrane components are the membrane lipids and the membrane proteins. Much of the attention will be focused on the membrane lipids here because many of them (though not all) contain phosphate as part of their structure, thus making the phospholipids amenable to study by ³¹P NMR. However, at the end, some consideration will be given to membrane proteins, since it is now possible to obtain ³¹P NMR spectra of the phosphorylation sites of membrane proteins.

The chemical structure of a phospholipid, phosphatidylcholine, is given in Figure 1. This is an amphipathic molecule. The end consisting of the lipid hydrocarbon chains is highly hydrophobic (many different kinds of hydrocarbon chains are found in nature). The other end of the molecule, consisting of the phosphate and the alcohol (or remainder of the polar headgroup), is polar (many different kinds of headgroups are found in nature). The phosphate, with its negative charge, is located in the polar headgroup of the molecule. Phosphorus-31 NMR therefore reports, most directly, on the behavior of the polar headgroup of the phospholipid.

The lipid bilayer is the fundamental structural component of biological membranes. The lipid bilayer is also spontaneously formed by many phospholipids in aqueous suspension, including phospholipids extracted from cell membranes. In the case where the cross-sectional area of the headgroup is similar to the cross-sectional area of the hydrophobic region of the molecule (the packing ratio, $P_r = A_h/A_c$, where h refers to the headgroup and c refers to the hydrocarbon chain region) $P_r \approx 1$, and the phospholipid shape can be approximated as a cylinder. The hydrophobic effect demands that the hydrophobic region of the phospholipid be sequestered from the water. Packing of the cylinders into a bilayer satisfies the thermodynamics of the hydrophobic effect. Thus the lipid bilayer, which is the fundamental structural element of all cell membranes, is a structure that spontaneously results from the chemical structure of the phospholipid and the hydrophobic effect (see Figure 2). These factors play important roles in the shape of the ³¹P powder patterns obtained from phospholipid assemblies.

Phosphorus-31 NMR, because of the high natural abundance of the ³¹P isotope, has been employed to study both model

Figure 1 Structure of phosphatidylcholine, a common membrane phospholipid

Figure 2 Schematic representation of assembly of phospholipids into bilayers when $P_r = 1$

and biological membranes. Some consideration of the physical structure of these systems is important to an understanding of the ^{31}P NMR powder patterns that are observed in the study of membranes.

The sonicated, unilamellar phospholipid vesicle (SUV) was used extensively in studies of lipid properties in bilayers.⁹ The SUVs are surrounded by a single bilayer and are 210–150 Å in diameter. The rotational correlation time for SUV is close to 10^{-6} s. This correlation time is short enough to cause extensive isotropic motional averaging of the elements of the phosphorus chemical shift tensor at most field strengths, and isotropic resonances are normally observed from phospholipids in SUVs, centered on the isotropic chemical shift of the phospholipid in the vesicle.

Another system that gives rise to isotropic chemical shifts is the detergent micelle. In this case the $P_r > 1$. The result is an approximately cone-shaped molecule, which, when packing to satisfy the hydrophobic effect, forms a micelle (roughly spheroid in shape). The isotropic chemical shifts of some of the most common phospholipids (solubilized in detergent) are given in Table 1.¹⁰

Probably the most common model membrane system to be studied by ^{31}P NMR is the multilamellar liposome (MLV). This is a much larger (than the above mentioned structures) phospholipid assembly, consisting of concentric bilayers of phospholipid and exhibiting diameters of 10 000 Å or more. Rotational correlation times of such structures are in the seconds range. Thus these MLVs do not permit sufficient motional averaging to produce isotropic ^{31}P NMR resonances from the phospholipids.

Biological membranes are usually isolated from tissue or cell suspension and consist of vesicles that are heterogeneous in size. Usually the size of these vesicles leads to rotational correlation times long enough for isotropic motional averaging not to occur. However, it is not unusual for smaller vesicles to form during the isolation procedures. These smaller vesicles have much shorter rotational correlation times than the MLVs, for example, and may produce isotropic resonances in the ^{31}P NMR spectrum. Such vesicles could interfere with the correct interpretation of lineshapes in the ^{31}P NMR spectrum, and the researcher should always be alert to such effects. Usually, electron microscopy or gel filtration chromatography is required to distinguish between the possible interpretations in such situations.

2.2 Characteristic NMR Properties

The membranes of cells describe a largely two-dimensional world, with only a limited third dimension. This structure influences the nature of the ^{31}P NMR spectra obtained from membranes. The lipid components diffuse laterally in the plane of the membrane as long as the membrane is liquid crystalline, except when lateral diffusion is inhibited by membrane proteins. Membrane lipids undergo rapid axial diffusion, usually with the director oriented perpendicular to the membrane surface. Time dependence of the orientation of the director (or wobble) is also observed. Internal motions, associated with rotations about single bonds within the lipid molecule, can often be described by order parameters. However, it should be noted that translational diffusion in the third dimension (perpendicular to the plane of the membrane) is severely restricted by the hydrophobic effect. These properties lead to a membrane structure that is highly anisotropic.

The ^{31}P chemical shift tensor is anisotropic. Measurements of the principal elements of the chemical shift tensor have been made for both simple organic phosphodiester and phospholipids in dry powders. The results of these measurements are given in Table 2. The full range of the chemical shift tensor is over 200 ppm ($\sigma_{33} - \sigma_{11}$) for phospholipids. In bilayers, rapid axial diffusion leads to a partial motional averaging of the ^{31}P chemical shift tensor. A pseudoaxially symmetric powder pattern is observed, characteristic of phospholipid bilayers (see Figure 3).

2.3 Technical Challenges

The powder patterns that arise from phospholipids in bilayers (that do not undergo rapid isotropic rotational diffusion) can easily be distorted due to instrumental conditions during accumulations of the FIDs. Inadequate ^1H decoupling is one source of such distortions that can lead to loss of the characteristic edges of the powder patterns and incorrect interpretations in static systems. The static ^1H – ^{31}P dipolar interaction is of the order of 6 kHz.¹¹ However, in the liquid crystalline state, rapid axial diffusion partially motionally averages the ^1H – ^{31}P interactions, so ^1H decoupling in the liquid crystalline state is rarely a serious problem.

The most common source of spectral distortions arises from instrumental artifacts common on non-solid-state spectrometers. The powder patterns obtained from model and biological membranes are broad. As a result the decay of the signal in the time domain from these powder patterns is rapid. Instrumental limitations often lead to a loss of the early portion of the FID, which contains the most crucial information for defining the spectral shape and intensity of the ^{31}P NMR powder pattern. As a result, most ^{31}P NMR powder patterns reported from membranes contain distortions. The broader the component, the more likely the ‘loss’ of that component from the transformed spectrum. Thus broad, motionally restricted, components in ^{31}P NMR spectra are easily missed. This problem can be rectified, at least in part, by using a fully phase-cycled Hahn echo.¹²

Another problem can arise from alteration in the T_2 relaxation in the ^{31}P powder pattern. An alteration in T_2 , which is observed when the bilayer is perturbed (such as in the presence of membrane proteins)¹³ will change the shape of the ^{31}P

NMR powder pattern. In some cases, an idealized lineshape has been reported which is incorrect (because of alteration of T_2 by the membrane proteins), but is observed because the early portion of the FID is missed in the data collection.

In the case of large MLVs and high magnetic fields, another 'distortion' of the ^{31}P powder pattern can be observed. This is due to orientation of the MLV in the magnetic field. Under these conditions, certain orientations become favored, and thus the ^{31}P powder pattern, which is only a summation of the relative populations of the possible orientations and the chemical shifts associated with those orientations, will change, reflecting the favored orientations in the magnetic field.¹⁴

2.4 Relaxation

Considerable progress has been made in the understanding of relaxation in ^{31}P NMR of membranes, but that understanding

Figure 3 Phosphorus-31 NMR spectra of phospholipid assemblies. Bottom: bilayer; top: H_{II} phase

is as yet incomplete. In principle, the spin–lattice relaxation of the phosphorus can be represented as:

$$\frac{1}{T_{1(\text{obs})}} = \frac{1}{T_{1(\text{DD})}} + \frac{1}{T_{1(\text{CSA})}} \quad (1)$$

where DD refers to dipolar interactions with protons and CSA refers to relaxation due to a time-dependent modulation of the chemical shift anisotropy. The available data suggest that at low fields, the first term is dominant¹⁵ and at higher fields, the latter term becomes dominant.¹⁶ As will be described below, the effective correlation times for the phosphate motion are around 1 ns. At some field strengths and temperatures, this means that T_1 relaxation is in the fast motion regime ($\omega_0\tau_c < 1$), or liquid-like when the membranes are liquid crystalline, yet the ^{31}P NMR spectra show powder patterns, which are solid-like. Thus, the researcher must carefully choose techniques from both high-resolution NMR and solid state NMR when studying ^{31}P NMR of membranes.

Given that the membranes give rise to ^{31}P powder patterns due to the ordered environment of the membrane, a valid question is whether the T_1 is anisotropic across the powder pattern. Such anisotropy has not been observed at low fields, because lateral diffusion of phospholipids through the orientations represented by the powder pattern is rapid. The latter was determined by saturation transfer experiments utilizing DANTE sequences.¹⁷ At high fields, some anisotropy is observed, where CSA relaxation dominates.¹⁶

Since T_1 can be measured in both SUVs and in MLVs, the question was raised of whether relaxation was any different in these two systems. While T_2 relaxation was most assuredly different in the two membrane systems, T_1 was not found to be significantly different.

3 MEMBRANE ASYMMETRY

3.1 Phospholipid Vesicles

Because SUVs produce high-resolution ^{31}P NMR spectra, distinguishable resonances are observed for many of the

phospholipids (by headgroup class) in SUVs. These vesicles are impermeable to cations. Therefore, the water-soluble shift reagent species of the lanthanide series can be selectively placed on one side of the vesicle membrane or the other. The lanthanides will alter the chemical shift of the ^{31}P NMR resonance from the phospholipid phosphates that they can contact through a scalar interaction. It is thus possible to alter selectively the isotropic chemical shift of the resonance from the phospholipids that inhabit the side of the membrane to which the lanthanide has access. With this technique, the resonance due to phospholipids in the inner leaflet of the vesicle membrane is separated from the resonance due to phospholipids in the outer leaflet of the vesicle membrane.¹⁸ A number of such studies have been reported and in some cases the distribution of phospholipid classes across the membrane is not uniform.^{19–21}

3.2 Potential Use of Magic Angle Spinning (MAS)

Magic angle spinning introduces the factor $(3 \cos^2\theta - 1)$ which, when the sample is at an angle of about 54.7° with respect to the external magnetic field, leads to averaging of CSA when the spinning is rapid compared with the breadth of the chemical shift tensor. Magic angle spinning ^{31}P NMR of unsonicated MLVs leads to isotropic resonances and some ability to distinguish individual phospholipid classes based on their respective isotropic chemical shifts.²² It is possible that this technology might be useful in the study of phospholipid asymmetry in biological membranes.

4 PHOSPHOLIPID HEADGROUP CONFORMATION AND DYNAMICS

4.1 Phospholipid Bilayers

Information on phospholipid headgroup conformation was obtained by exploiting the nuclear Overhauser effect (NOE) arising from the ^1H – ^{31}P dipolar interactions. At low field, the ^1H – ^{31}P dipolar interactions are relatively strong, due to the dominance of the dipolar interactions in the spin–lattice relaxation. These interactions were explored to determine which protons were most effective in relaxing the phosphorus. A pre-two-dimensional NOE study was performed with a variable frequency proton decoupling field, and the *N*-methyl protons of the phosphatidylcholine headgroup were found to be major contributors to the relaxation of the phosphorus.²³ This result led to the conclusion that the phospholipid headgroup was oriented parallel to the membrane surface. The NOE data also made clear that the phospholipid headgroups were engaging in intermolecular headgroup interactions, because, for example, the spin–lattice relaxation for the phosphate in phosphatidylethanolamine in mixed phosphatidylethanolamine/phosphatidylcholine bilayers was determined by dipolar interactions with the phosphatidylcholine *N*-methyl protons.

A combination of ^{31}P NMR and ^2H NMR powder pattern data were used to assign phospholipid headgroup conformation by an independent method. The conclusion was the same as in the NOE studies.⁷ These intermolecular interactions could be disrupted by cholesterol.

^{31}P NMR powder patterns from membranes are a result of the anisotropic structure of the lipid bilayer. The dominant motion of the phospholipids that determine the ^{31}P lineshapes is axial diffusion in the bilayer. The director for axial diffusion is ordered. Therefore, the effect of phospholipid motion in the membrane on the ^{31}P NMR lineshape can be described, to a first approximation, by application of a rotation matrix to the chemical shift tensor of the phosphorus. Such axial rotation leads directly to the axially symmetric powder pattern observed in the ^{31}P NMR spectra from phospholipid bilayers. However, the width of the powder pattern in the liquid crystalline state is less than that predicted from simple rotation of the ^{31}P chemical shift tensor. The simplest model to explain the observed powder pattern adds a time-dependence of the director for axial diffusion, or wobble, to the motion.²⁴

The NOE studies also indicated that the dominant correlation time for the phospholipid phosphate was about 1 ns, because the $^{31}\text{P}\{^1\text{H}\}$ NOE was motionally limited in its magnitude.¹⁵ This evaluation of correlation time was confirmed by later studies in which the T_1 relaxation was measured as a function of temperature. It was noted that at higher temperatures the ^{31}P nuclei in the phospholipid phosphates were behaving as if they were in the fast motion regime. Temperature provided a means of varying the dynamics of the system through thermally induced motion, moving from the fast motion regime toward the slow motion regime. A plot of T_1 as a function of temperature revealed a minimum.²⁵ This unambiguously determined a correlation time of about 1 ns for phosphate dynamics.

4.2 Effects of Gel–Liquid-Crystalline Phase Transition

When the phospholipid bilayer undergoes a phase transition from the liquid crystalline state to the gel state, the molecular dynamics change. This change is reflected in the ^{31}P lineshapes. Predictable increases in the breadth of the powder pattern are observed due to the motional restriction in the gel state.²⁶ In cross-polarization ^{31}P NMR spectra, distinctive lineshape changes occur as the headgroups ‘freeze’ into the gel state.²⁷ These data show that the headgroups behave somewhat independently of the hydrocarbon chains, as the ‘melting’ temperatures for motion in the headgroups are different from those in the hydrocarbon chains.

4.3 Effects of Ions

Ion binding to the phospholipid headgroups can cause changes in the ^{31}P NMR spectra. Cations can cause a shift of the ^{31}P phosphate resonance.²¹ Changes in headgroup conformation can also be induced by cations and are reflected in the ^{31}P powder pattern observed from negatively charged phospholipid phosphates.²⁸

4.4 Effects of the Radius of Curvature

The size of the phospholipid assembly will often influence the ^{31}P NMR lineshape, since isotropic tumbling of small radii of curvature particles will lead to motional averaging of the chemical shift tensor. This has been explicitly

measured using a variety of sized vesicles and measuring the lineshapes.²⁹ In the case of small vesicles, increasing the viscosity of the medium to reduce the tumbling rate of the vesicles can create a situation in which the motional averaging due to lateral diffusion around the surface of the vesicle can be measured. The diffusion coefficient obtained from such measurements agrees well with the diffusion coefficient obtained from measurements in MLVs by independent techniques.³⁰

5 PHOSPHOLIPID–PROTEIN INTERACTIONS IN MEMBRANES

5.1 Perturbations of Membrane Bilayer Properties by Proteins

At this point it is necessary to introduce the other major component of membranes, the membrane proteins. Of particular interest here are the integral, transmembrane proteins that have a portion of their mass integrated into the lipid bilayer. The question that has been of interest for many years is whether any of the phospholipids of the bilayer have specific interactions with the membrane proteins that have functional consequences. Although this has been a field of considerable controversy in the past, today there can be little doubt that at least some proteins have phospholipid binding sites that are specific for particular phospholipid structures. Among these are glycophorin, cytochrome oxidase, adenosine 5'-triphosphate–adenosine 5'-diphosphate (ATP–ADP) exchange protein, and the phospholipases.

5.2 Motionally Restricted Phospholipid Domains

The case of glycophorin is illustrative. A component of phospholipid is found bound to glycophorin when it is isolated from the erythrocyte membrane. This phospholipid is enriched with phosphatidylinositol.³¹ Other researchers have shown that the state of phosphorylation of this specifically bound phosphatidylinositol controlled the affinity of glycophorin for the membrane skeleton of the erythrocyte.³² Since ^{31}P NMR can in principle be sensitive to all the phospholipids in a sample, ^{31}P NMR should be able to reveal something of the dynamics of the phospholipids bound to glycophorin. Recent experiments have examined the properties of the phospholipids tightly bound to glycophorin by reconstituting the glycophorin with only the tightly bound phospholipids bound into a glycolipid bilayer. The ^{31}P NMR spectrum therefore arose only from the tightly bound phospholipids. The powder pattern obtained was an axially symmetric powder pattern, but much broader than that from pure phospholipid bilayers. It was concluded that the phospholipids bound to the protein were undergoing rotational diffusion with the protein in the membrane.³³

Another example can be found in the ATP–ADP exchange protein from mitochondria. This protein requires cardiolipin for activity. Recent ^{31}P studies revealed that cardiolipin is tightly bound to this enzyme. Only the action of a strong detergent, like sodium dodecyl sulfate is capable of disrupting these phospholipid–protein interactions.³⁴

5.3 Phospholipid Exchange Between Domains

Since membrane proteins, in some cases, create a distinguishable domain of motionally restricted phospholipids in membranes, one must ask whether there is exchange between the bound phospholipids and those of the surrounding phospholipid bilayer. In the case of glycophorin, the tightly bound phospholipids apparently exchange only slowly with the glycolipids. For the calcium pump protein of sarcoplasmic reticulum, the exchange rate was measured using magnetization transfer. A rate of 1 s^{-1} was measured.³⁵ These exchange rates are slow, but no slower than phospholipid exchange between nonlamellar and lamellar phases in the same sample.

5.4 Reconciliation of ^{31}P NMR Data with Other Magnetic Resonance Data

Deuterium NMR experiments with deuterated phospholipids have not shown a component of motionally restricted phospholipid in the presence of membrane proteins. An important question is how to reconcile those results with the ^{31}P NMR results. This is understood in terms of protein motion in the membrane. Correlation times for protein axial diffusion in the membrane are of the order of 10^{-4} to 10^{-5} s. Motion on this timescale has been shown to cause artificial attenuation of the spectral intensity for ^2H NMR of deuterated lipids. This is the result of a fast decaying echo in the solid echo experiment used for the ^2H NMR experiments.³⁶ As a specific example, rhodopsin was reconstituted with a specifically deuterated phospholipid. In the ^{31}P NMR spectrum two overlapping powder patterns were observed, one due to motionally restricted phospholipid interacting with the protein. With ^2H NMR of the same sample, only one spectral component was observed, that due to the normal phospholipid bilayer surrounding the protein.³⁷ Thus ^2H NMR is not a good technique to probe properties of lipids interacting with membrane proteins, as any tightly bound lipids will be invisible in the ^2H NMR spectrum. However, at least in some cases, ^{31}P NMR is sensitive to the bound phospholipid component.

6 MEMBRANE MORPHOLOGY

As indicated above, the lamellar (bilayer) phase gives rise to characteristic ^{31}P NMR powder patterns (see Figure 3). These powder patterns are the result of motional averaging of the ^{31}P chemical shift tensor. The dominant motion in the lipid bilayer influencing the shape of the bilayer powder pattern is axial diffusion about a director approximately perpendicular to the membrane surface (which is further modulated by a wobble of the director). It would be expected that in phospholipid assemblies with different structures and different modes of motion available, that the powder patterns might be different. The hexagonal II (H_{II}) phase provides an example.

6.1 ^{31}P NMR of Hexagonal II Phase

The H_{II} phase is a nonlamellar phase that is readily formed by some biological phospholipids, including phosphatidylethanolamine. The H_{II} phase consists of tubes, each

containing a small aqueous channel, with the phospholipid headgroups directed inward toward the aqueous channel. The hydrocarbon chains are directed toward the exterior of the tubes. The tubes of the H_{II} phase are stacked with the hydrocarbon surfaces of the tubes in close apposition. These cylinders are small in diameter. Typically the diameter of the aqueous channel is 20–30 Å. With a common diffusion coefficient for lateral diffusion of $10^{-8} \text{ cm}^2 \text{ s}^{-1}$, circumnavigation of the cylinder occurs with a correlation time of about 10^{-6} s. This is sufficiently rapid to introduce an additional degree of motional averaging of the chemical shift tensor. All other things being equal, this motional averaging produces a lineshape with half the breadth of the bilayer powder pattern and with an apparent reversal of the lineshape (see Figure 3). The older literature on this subject has been reviewed.³⁸ Much work was done, utilizing the ability of ^{31}P NMR to determine readily the extent of lamellar and H_{II} phase structures in a sample, to characterize the factors that regulate the L_{α} – H_{II} phase transition.

Current interest in this subject has focused on the observation of intermediate structures on the pathway of the L_{α} – H_{II} phase transition (this subject has been recently reviewed³⁹). These can be seen as part of the phase diagram of some mixtures of phospholipids that undergo the L_{α} – H_{II} phase transition. These intermediate structures appear as isotropic resonances in the ^{31}P NMR spectra and are not detected in X-ray diffraction of these samples, pointing to the usefulness of ^{31}P NMR. Freeze fracture electron microscopy of these samples reveals that the isotropic ^{31}P resonances arise from interlamellar attachments made of phospholipids. In some systems, these intermediates are the result of the initiation of membrane fusion, and thus have been studied with ^{31}P NMR to obtain clues as to the intermediates on the membrane fusion pathway.

6.2 NMR of Isotropic Phases

The above discussion has already introduced the topic of isotropic ^{31}P NMR resonances from phospholipid dispersions. One means of obtaining an isotropic ^{31}P NMR resonance is to create a phospholipid assembly sufficiently small that isotropic tumbling of the assembly can average the expression of the ^{31}P chemical shift tensor. The SUV is one example. Another example is provided by the intermediate structures just described. Here the movement of the phospholipid phosphate through an angle of 90° on the surface of the intermediate structure is sufficiently rapid to average the expression of the chemical shift tensor. Another example is provided by the cubic phase.⁴⁰ Trivial examples are seen in the case of solution phase phospholipids (such as in methanol/chloroform) and in detergent micelles.

6.3 Domains and the Exchange of Lipids between Domains

The ^{31}P NMR spectra of phospholipid dispersions with complex morphology can produce overlapping powder patterns characteristic of each of the phases present. The simultaneous observations of powder patterns from as many as three different structures (for example, lamellar, H_{II} , and isotropic) are commonly observed. These observations suggest that exchange

between these structures is slow. Using magnetization-transfer ^{31}P NMR, this question was explicitly addressed and the conclusion reached that exchange between the structures was slow on the seconds timescale.⁴¹

7 MEMBRANE PROTEIN PHOSPHORYLATION

All of the above discussion focused on the phospholipid component of biological membranes, exploiting the power of ^{31}P NMR and the naturally occurring phosphorus in the phosphate of every phospholipid. There is another location for phosphorus in biological membranes. Phosphorus is found on some membrane proteins when these membrane proteins have been phosphorylated by cellular kinases. Phosphates can be found on serine, threonine, and tyrosine, depending upon the particular kinase that is active. In principle, it should be possible to probe these phosphorylation sites with ^{31}P NMR. Since these sites are attached to membrane proteins, their motion would be expected to be severely restricted. Therefore MAS ^{31}P NMR was used to search for resonances due to protein phosphorylation sites. Recent experiments using this approach demonstrated the ability to visualize phosphorylation sites on the membrane protein rhodopsin.²² Chemical shift dispersion may prove to be sufficient to distinguish different sites of phosphorylation, according to class of kinase activity.

1 INTRODUCTION

This article summarizes what has been learnt up to 1994 about the internal flexibility and motion of DNA and RNA from NMR studies of solid poly- and oligonucleotides. Although *in vivo* high molecular weight nucleic acids, such as ribosomes, nucleosomes, and viruses, are often found in environments that are more solid-like than liquid-like, relatively few—30+ at last count—NMR studies of solid nucleic acids have been published. Of these, only half are concerned with the internal dynamics, but the results accumulated so far are of basic interest as a test of theories of biopolymer motion. They are also useful to practitioners of high-resolution NMR structural studies of oligonucleotides and nucleic acid/protein complexes because they complement the structural data obtained from X-ray diffraction studies with information about rates and amplitudes of internal motion.

So far the major tools for obtaining information about the dynamics of nucleic acids have been ^2H and, to a lesser extent, ^{31}P NMR lineshape simulations and relaxation measurements. DiVerdi and Opella¹ reported the first deuterium quadrupole echo spectra of high molecular weight DNA. Their nearly full width powder spectra of calf thymus DNA labeled at the purine C-8 positions suggested that the base pairs are quite immobile at 20°C, but a drop in quadrupole echo intensity at 50°C indicated the onset of librational motion at this temperature. Subsequently James and co-workers^{2,3} obtained similar wide spectra of solid poly(I)-poly(C) deuterated at inosine C-8, but a short spin-lattice relaxation time T_1 clearly indicated the presence of small angle librational motion. In addition, the quadrupole echo decay time T_{2e} was observed to drop with increasing humidity, to a point where the ^2H quadrupole echo spectrum would vanish completely and then reappear as a single line only after a regular solution state was achieved. Apparently, some slow, large angle dynamic process set in as the polynucleotide absorbed water.

Phosphorus solid state NMR spectroscopy was initially used for studies of DNA backbone conformation by Shindo et al.⁴ and Nall et al.,⁵ who observed little internal motion at moderate humidities, but the onset of large angle, slow motion above 90% relative humidity (RH). Opella and co-workers also

used ^{31}P solid state NMR spectroscopy to illustrate the absence of large angle motion in chromatin,⁶ in viral DNA,^{7,8} and viral RNA.⁹ More recently, two-dimensional ^{15}N and ^{13}C NMR spectroscopy has been used in studies of high molecular weight DNA,^{10,11} but here the emphasis was solely on structural elucidation.

When most of the water bound to nucleic acids is removed, the regular helical structure distorts.¹² The resulting disorder, and its reversibility upon exposure of dry DNA to moisture, has been documented by ^2H NMR studies of oriented samples of Li-DNA.¹³ The extent of water uptake, w , as a function of atmospheric humidity is shown in Figure 1 for both Na-DNA, which takes the A-form below 85% RH, and Li-DNA, which retains a regular B-form down to 50% RH. As also illustrated in Figure 1, the hydration of DNA has a strong effect on the ^{31}P spin-lattice relaxation times as first demonstrated in 1983 for high molecular weight calf thymus DNA. Mai et al.¹⁴ showed that the phosphate backbone of completely dry (lyophilized) DNA is quite rigid, and that the amplitude of backbone motion increases continuously, if not uniformly, as the water content of the material is increased from 0 to 33 mol of water per nucleotide. Figure 1 shows that the ^{31}P spin-lattice relaxation rate R_1 increases by a factor of roughly 500-times as 20 mol of water is absorbed, and an R_1 maximum observed at 90% RH shows that some motional process with an *effective* correlation time of 10^{-9} s is present at this level of hydration, which corresponds to a point where Na-DNA has

Figure 1 Water content, w , of Na-DNA (○) and Li-DNA (●) as a function of relative humidity (% RH). The water uptake by the two salts is quite similar, but Na-DNA undergoes a transition from the B- to the A-form as the humidity is reduced below 85% RH while Li-DNA retains the B-form until ca. 20% RH. The ^{31}P spin-lattice relaxation rate ($\times 10$) for calf thymus DNA (Na salt) measured by Mai et al.¹⁴ is included to show the dramatic effect of hydration on the extent of internal motion in DNA

changed from the A- to the B-form. On the basis of the ^{31}P lineshapes, the authors concluded that this motion involved twisting of the DNA molecule by at least 30° about the helix axis, quite likely corresponding to torsional modes^{15,16} observed in optical studies of DNA in solution.

A ^{31}P spectral lineshape analysis was undertaken in 1985 by Fujiwara and Shindo,¹⁷ and their results basically agreed with the conclusions of Mai et al.¹⁴ The mode of motion found to influence the spectra most strongly at high humidity (92% and 98% RH), was confirmed as rotation about the helix axis with a rate of $1-5 \times 10^4 \text{ s}^{-1}$, and the onset of this motion presumably leads to the breakup of the fiber structure as interstitial water permits individual helices to rotate relative to one another.

Deuterium NMR studies of polynucleotides began in earnest in the mid-1980s with studies by Shindo et al.¹⁸ and by Vold and Kearns and their co-workers,^{19,20} while the Drobny group^{21,22} focused on the dynamics of oligonucleotides. The deuterium work, summarized below, was aimed at elucidating the nature of the librational motion of the base pairs and the conformational flexibility of the sugar moieties at humidities below 98% RH. A review by Alam and Drobny²² should be consulted for details. Since that review was published in 1991, two papers on deuterium relaxation and internal motion in poly- and oligoribonucleotides have appeared^{23,24} which document the higher rigidity of solid RNA compared with DNA. For comparison with relaxation and molecular dynamics of nucleic acids in solution, two reviews by James²⁵ and Lane²⁶ are available.

2 DEUTERIUM QUADRUPOLE ECHO SPECTRA OF POLY- AND OLIGONUCLEOTIDES

The resonance frequency of a deuteron in a solid material is a function of the quadrupole coupling constant χ and the asymmetry parameter η of the quadrupole coupling tensor; of the orientation relative to the external magnetic field of an X-D bond (X = C, N, or O); and of the amplitude and rate of any motion of this bond. For C-8 deuterated base pairs in nucleic acids, the relevant quadrupole coupling parameters have been determined to be $\chi = 179 \pm 1 \text{ kHz}$, $\eta = 0.07 \pm 0.01$ from quadrupole echo spectra of very dry DNA¹⁹ and suitable, 'rigid' model nucleosides.²⁷ The principal component of the quadrupole coupling tensor, χ_{zz} , is very nearly collinear with the bond and if no motion occurs the two deuterium transitions can be observed at

$$\nu_{\pm} = \pm \frac{3}{4} \chi \left[\frac{1}{2} (3 \cos^2 \beta - 1) + \frac{\eta}{2} \sin^2 \beta \cos \gamma \right] \quad (1)$$

where $\beta = \beta_{lp}$ and $\gamma = \gamma_{lp}$ are the Euler angles relating the orientation of the principal axis system of the quadrupole coupling tensor (p) in a coordinate system (l) fixed in the laboratory and defined by the direction, z_l , of the magnetic field. The angles β_{lp} and γ_{lp} are illustrated in Figure 2 for a deuteron in the C-8 position of an idealized GC base pair. The lineshape of the deuterium NMR spectrum of a 'rigid' solid sample may be calculated from equation (1) by summing contributions from all possible values of β and γ .

Deuterium powder spectra of calf thymus DNA recorded as a function of humidity^{2,18,19} showed that hydration results

Figure 2 Four coordinate systems, l for laboratory, h for helix, b for base pair, and p for the principal axis system of the deuterium quadrupole coupling tensor, are necessary for describing the orientation and internal motion of the base pairs in nucleic acids. Specifically shown are the Euler angles relating the orientation of the deuterium quadrupole coupling tensor to the magnetic field direction along z_l . Also included are the tilt (θ), roll (ρ), and twist (ϕ) angles for the base pairs, and the amplitudes of libration, θ_0 and ϕ_0 used to model the librational motion of base pairs relative to the helix orientation

in small, but unmistakable changes in the apparent χ and η . In order to account for these changes, a model of C-D bond libration in two orthogonal planes, one containing the base pair and one containing the helix axis and the C-D bond, was introduced. With the additional assumption of uniform distribution of θ and ϕ within the ranges $-\theta_0 \leq \theta \leq \theta_0$ and $-\phi_0 \leq \phi \leq \phi_0$ (see Figure 2), the deuterium frequencies in B-form DNA with $\langle \theta \rangle = 90^\circ$ and $\langle \theta \rangle = 0^\circ$ is still given by equation (1), but with *effective* quadrupole coupling parameters

$$\chi_{\text{eff}} = \frac{\chi}{4} \left[1 - \eta - (3 + \eta) \frac{\sin 2\theta_0}{2\theta_0} \right] \quad (2)$$

and

$$\eta_{\text{eff}} = -\frac{\sin 2\phi_0}{2\phi_0} \cdot \frac{(\eta - 1) + (3 + \eta) \sin 2\theta_0/2\theta_0}{3(\eta - 1) - (3 + \eta) \sin 2\theta_0/2\theta_0} \quad (3)$$

and $\beta = \beta_{lh}$ and $\gamma = \gamma_{lh}$ defining the orientation of the two planes in the laboratory frame. A typical ^2H quadrupole echo spectrum of partially hydrated B-form Li-DNA is presented in Figure 3 together with theoretical spectra (dashed and dotted curves) calculated¹⁹ according to equations (1)–(3). Comparison of the experimental and calculated spectra show that the librational amplitudes at 66% RH are $\theta_0 = 8 \pm 2^\circ$ and $\phi_0 = 12 \pm 2^\circ$.

The librational amplitudes in purine C-8-deuterated DNA were determined more accurately as a function of humidity from ^2H quadrupole echo spectra of C-8-deuterated, folded, oriented films of calf thymus DNA.¹³ The spectra of a 75% RH Li-DNA sample oriented with the helix axis parallel with [Figure 4(a), $\beta_{lh} = 0^\circ$] and perpendicular to [Figure 4(b), $\beta_{lh} = 90^\circ$] the magnetic field are shown in Figure 4. Simulations of such spectra¹³ show that the purine C-8-D bond is oriented at $90 \pm 1^\circ$ from the helix axis and that the samples are quite well ordered with a Gaussian distribution in helix and/or base pair orientation of less than 9° when $w \geq 6$. The results of fitting the spectra to yield amplitudes of motion are shown in

Figure 3 Deuterium quadrupole echo NMR spectrum of calf thymus Li-DNA (5.9% excess LiCl). The spectrum (with $T_1 = 200 \pm 10$ ms, $T_{2e} = 250 \pm 50 \mu\text{s}$) was obtained at 38.4 MHz, 25 °C and 66% RH¹⁹ from 64 000 quadrupole echoes using an 8-step phase cycled sequence $\pi/2_x, \tau, \pi/2_y, \tau, \text{acq}$ with a $\pi/2$ pulse length of $2.0 \mu\text{s}$ and $\tau = 30 \mu\text{s}$. A 2 kHz Gaussian line-broadening function was used for signal-to-noise enhancement. Superimposed on the experimental spectrum are two simulations calculated as described in the text according to equations (2)–(4) with libration amplitudes that define the uncertainty ($\pm 2^\circ$) in fitting the experimental spectra. The discrepancy between experimental and calculated spectra intensity near the center arises because the spectra were calculated without including transverse relaxation, and the ‘spike’ near $\nu = 0$ arises from natural abundance ^2H in normal water

Figure 5. Below $w = 13\text{H}_2\text{O}/\text{nucleotide}$ (84% RH) neither libration angle exceeds $\pm 15^\circ$, and the amplitude of the twist motion is slightly larger than that of the tilt motion. Also shown in Figure 4 [(c) and (d)] are the ^2H spectra of oriented Na-DNA. The spectra show²⁸ that the bulk of the sample has the expected A-form and the angle between the C–D bond and the helix is $67 \pm 1^\circ$, also with a Gaussian distribution of 9° in the helix and/or base pair orientation. However, some of the DNA is present in the B-form. This component shows up in the X-ray diffraction patterns only as diffuse background scattering, because this component is dispersed and nondiffracting.

Above 85% RH, w increases rapidly (see Figure 1), and the spectral signal-to-noise ratio worsens because the quadrupole echo dephases rapidly. This shortening of T_{2e} , from $400 \mu\text{s}$ to less than $100 \mu\text{s}$ at high humidities, shows that a slow motion with an effective correlation time $\tau_c \sim 10^{-6} - 10^{-4}$ s is present, in agreement with the earlier ^{31}P results.¹⁴ Shindo et al.¹⁸ explored the effects of higher humidity (92% RH) on the deuterium lineshapes of oriented B-form samples of Na-DNA, and established that T_{2e} is much longer at $\beta_{lh} = 0^\circ$ than at other helix orientations. This implies that the slower motion responsible for the short T_{2e} takes place in a plane perpendicular to the helix axis, and their simulations suggested that at 92% RH the amplitude of this torsional motion is on the order of 60° . As even more water is absorbed, the DNA fibers begin to dissolve and complete reorientation about the helix axis takes place.

Deuterium quadrupole echo spectra obtained by Drobny and co-workers²² of selectively deuterated samples of the dodecamer duplex $[\text{d}(\text{CGCGAATTCGCG})_2]$ present a similar

Figure 4 Deuterium quadrupole echo spectra of oriented folded films of the Li salt [(a) and (b)] and Na salt [(c) and (d)] of calf thymus DNA obtained at 75% RH and otherwise under conditions as described for Figure 3, except that 1 kHz line broadening was applied to (a), (c), and (d). Spectra (a) and (c) were recorded with the helix axis parallel to the magnetic field, while in (b) and (d) the helix axis was perpendicular to the field. The number of transients required was (a): 70 000; (b): 280 000; (c): 112 000; and (d): 190 000

Figure 5 Amplitudes of libration θ_0 (circles) and ϕ_0 (squares) plotted as a function of water content and obtained by fitting spectra of macroscopically oriented Li-DNA fibers¹³ such as those shown in Figure 4. The experimental uncertainty in the amplitudes is $\leq 1^\circ$

picture of the internal motion in nucleic acids. Nearly full width powder patterns were observed below $w \sim 10$ for several base labeled isotopomers and a four-site jump model, corresponding to libration with increasing amplitude in two orthogonal directions, could account for the data in the lower hydration range. Above $w \sim 10$ ($>80\%$ RH) the echo intensity

was observed to drop and the lineshapes indicated the influence of large angle restricted rotation about the helix axis with rotational correlation times on the order of $10\ \mu\text{s}$, just as was found for highly hydrated high molecular weight DNA. The spectra of a methyl deuterated dodecamer were found to be particularly informative because of the better signal-to-noise ratio associated with having six deuterons per molecule and a spectrum narrowed by rapid methyl rotation. Thus, an isotropic peak was observed in the thymidine CD_3 spectra above 90% RH, as complete, nearly isotropic reorientation of the short (aspect ratio 1.7) dodecamer set in.

Spectra obtained by Huang et al.²⁹ for a dodecamer sample deuterated in the C-2' position (2''-d) of adenosines 5 and 6 support the analysis of the base pair data. The intrinsic asymmetry parameter η is very small for aliphatic deuterons, and since the spectra remain nearly cylindrically symmetric below 88% RH, the small angle libration of the 2'' deuteron responsible for spectral narrowing must be uniaxial as well. Lineshapes obtained between 80% and 92% RH showed that the only large angle motion was that of overall molecular reorientation about the helix axis. In particular, Huang et al.²⁹ found no evidence for fast ($>10^3\ \text{s}^{-1}$) 2'-endo to 3'-endo conformational exchange of the furanose ring.

3 DEUTERIUM RELAXATION MEASUREMENTS AND RATES OF INTERNAL MOTION

Information about the rate of the librational motion in solid nucleic acids has been obtained from ^2H spin-lattice relaxation measurements on Na and Li salts of calf thymus DNA^{20,30} and synthetic poly-²⁴ and oligo-²³ ribonucleotides. As shown in Figure 6 for the polymers, R_1 grows steeply with hydration, paralleling the increase observed for ^{31}P R_1 ,¹⁴ and the motion responsible for this increased relaxation efficiency must be the small angle libration described above. It is quite clear from the data in Figure 6, and similar measurements on oligonucleotides,²³ that the internal motion in RNA provides a less efficient relaxation mechanism than in DNA. As pointed out by Wang et al.,²³ this difference is matched in the solution relaxation behavior of oligoribo- and deoxyribonucleotides. At this point it is not entirely clear whether this is due to a smaller amplitude or a lower rate of motion in RNA. The relaxation rate associated with small angle libration is roughly proportional to the square of the amplitude of the motion, and calculated relaxation rates are therefore very sensitive to small changes in spectral splittings, which are hard to detect in powder spectra with limited signal-to-noise ratios. The libration in poly(G)-poly(C) was also observed to be slightly less effective in relaxing the C-8 deuterons than in poly(A)-poly(U) and poly(I)-poly(C), possibly because of the triple hydrogen bond reducing any propeller motion of the base pairs, but the difference is barely outside the experimental uncertainty of the measurements.

The frequency dependence of the spin-lattice relaxation rate in Li-DNA illustrated in Figure 6 proves that the librational motion observed below 84% RH is characterized by effective correlation times longer than approximately 1 ns. Treating this restricted motion as a diffusional process with a Lorentzian spectral density function yields a rotational diffusion constant $D \sim 10^6\ \text{s}^{-1}$. However, the ratio, $R_1(38.4\ \text{MHz})/R_1(76.8\ \text{MHz})$

Figure 6 Spin-lattice relaxation rates R_1 of Li- and Na-DNA and three synthetic polyribonucleotides, poly(A)-poly(U), poly(G)-poly(C), and poly(I)-poly(C), measured at 76.8 and 38.4 MHz and plotted as a function of water content, w . The relaxation rates were measured at the perpendicular edges of the powder patterns by the 'saturation-recovery' method, i.e. by varying the recycling delay between individual quadrupole echo pulse sequences.^{19,24} It should be noted that the recovery curves were always slightly nonexponential as expected from overlapping transitions and T_1 anisotropy. The water content was determined gravimetrically, and below $w = 5-6$ systematic errors in w may be present because the dehydrated polymers absorb water very quickly

~ 2 observed between data obtained at 5.9 T and 11.8 T shows that a diffusional process, which predicts a value of four for this ratio, cannot account for the relaxation data. Further insight into the nature of this motion has been gained from measurements²⁰ of the individual spectral densities, $J_1(\omega_0)$ and $J_2(2\omega_0)$, of the librational motion. The quantities $J_1(\omega_0)$ and $J_2(2\omega_0)$ were obtained using the Jeener-Broekaert pulse sequence³¹ from measurements of the rate of recovery of Zeeman order R_{1Z} (equal to the familiar spin-lattice relaxation rate, R_1) and the rate of decay of quadrupolar order R_{1Q} according to the expressions³²

$$R_{1Z} = \frac{3\pi^2}{2} \chi^2 [J_1(\omega_0) + 4J_2(2\omega_0)] \quad (4a)$$

$$R_{1Q} = \frac{9\pi^2}{2} \chi^2 J_1(\omega_0) \quad (4b)$$

Spectral density data obtained for samples of Li-DNA oriented with the helix axis parallel to the magnetic field ($\beta_{lh} = 0^\circ$) at 76.8 and 38.4 MHz and presented in Figure 7 show that $J_1(\omega_0)$ is consistently larger than $J_2(2\omega_0)$. This result rules out in-plane, torsional motion about the helix axis as the dominant

Figure 7 Spectral densities of motion for Li-DNA at 76.8 and 38.4 MHz, $\beta_{\text{H}} = 0^\circ$, 25°C as a function of water content. The quantities $J_1(\omega_0)$ and $J_2(2\omega_0)$ were determined from R_{1Q} and R_{1Z} in a Jeener–Broekaert experiment

relaxation mechanism²⁰ below 84% RH, but as the humidity is increased the ratio $J_1(\omega_0)/J_2(2\omega_0)$ drops indicating increasing contributions from torsional motion. Both spectral densities are also seen to be frequency-dependent with $J_2(2\omega_0)$ showing the larger effect of changing field, but the frequency-dependence is too weak to reflect a diffusional process with effective correlation times longer than 1 ns. Instead, it is likely that the $\sim\omega_0^{-1}$ frequency-dependence is due to collective bending motions of the polymer as described by Barkley and Zimm¹⁵ and Schurr.³³

Brandes et al.¹⁹ noted that the ratio of ^{31}P and ^2H spin–lattice relaxation times did not change as a function of hydration level in high molecular weight DNA. Similarly, Huang et al.²⁹ showed that the ratio between deuterium T_1 values for base pair and furanose $2''$ -deuterons in the oligonucleotide was constant. This strongly suggests that in both poly- and oligomers the relaxation active motions of base pair, sugar, and phosphate backbone are coupled at nearly all levels of hydration. This is an interesting observation because it agrees with a similar conclusion drawn by Holbrook and Kim³⁴ from a segmental motion analysis of the X-ray data for the dodecamer.

4 SUMMARY

On the basis of deuterium lineshape analysis and relaxation measurements, one can draw the following picture of the dynamics in solid DNA and RNA. In fully dehydrated poly- and oligonucleotides, all internal motion is very highly restricted, amounting to at most 4 – 6° of very fast libration, since full-width powder patterns are observed and the

spin–lattice relaxation times are quite long. For both base pairs and sugar moieties, moderate water uptake is accompanied by librational motion of increasing amplitude, but below $w \sim 10$ – $15\text{H}_2\text{O/nucleotide}$ the amplitude does not exceed ca. 15° . The application of different models, such as finite jumps or restricted diffusion, leads to slightly different estimates of this maximum librational excursion, but for all parts of the nucleic acid molecule—base pair, sugar, and phosphate backbone—there is no evidence for fast, large angle, local motion. The base pair motions in poly- and oligonucleotides appear to be very similar and the motion can be modeled as librations of roughly similar magnitude in two planes, parallel and perpendicular to the base pairs. The libration is fast compared to the width of the deuterium spectrum, i.e. $>10^5\text{ s}^{-1}$, with significant density near the Larmor frequency. This follows from the observation of a substantial increase in the rates of both ^2H and ^{31}P spin–lattice relaxation and the measurement of frequency-dependent relaxation rates for high molecular weight Li-DNA. The observation of a ratio of ca. 2 for T_1 at 38.4 MHz and T_1 at 76.8 MHz shows that this motion cannot be characterized as a simple process with an exponential correlation function. Furthermore, frequency-dependent measurements of the individual spectral densities of motion, $J_1(\omega_0)$ and $J_2(2\omega_0)$, for oriented Li-DNA has proven that the motion dominating the relaxation at humidities below ca. 80% RH is a wobble of the base pair normal, perhaps of the local helix axis, rather than torsional motion about the helix axis. A comparison of relaxation data for deoxyribo- and ribonucleotides showed that the librational motion in RNA is less relaxation-active than in DNA. Whether this is due to a difference in librational amplitude or a difference in rate of motion has yet to be ascertained.

At high humidity the deuterium lineshapes and short T_{2e} values show that a slow dynamic process sets in. The process is characterized by effective correlation times in the 1 – $100\text{ }\mu\text{s}$ range, and consists of torsional motion, or molecular reorientation, about the helix axis. Finally, as the humidity is increased even more to the point where the sample is a viscous gel-like material, T_{2e} is so short that no deuterium quadrupole echo spectra can be observed, except in the case of the methyl-deuterated dodecamer. The CD_3 spectrum, like the ^{31}P spectra of the polymer, is reduced to an isotropic line, which indicates the onset of large angle fluctuations in all directions as the nucleic acid dissolves. The classification of these fluctuations as either internal or overall motion has yet to be made categorically, but all experimental data obtained so far suggest that heavily hydrated DNA is highly flexible.

1 INTRODUCTION: CHOLESTEROL AND MODEL MEMBRANES

Cholesterol and related structures are distributed ubiquitously in the membranes of living organisms. Cholesterol is a major component of mammalian plasma membranes and plasma lipoproteins. Cell surface membranes, some viral membranes, and specialized cell membranes such as myelin contain large amounts of cholesterol, having as much as equimolar amounts of cholesterol and phospholipids. On the other hand, subcellular membranes tend to have less cholesterol, with the inner mitochondrial membrane having a very low cholesterol content.^{1,2} Cholesterol levels are altered in the membranes of some pathophysiological states such as malignant lymphoid cells.³ Cholesterol plays many important roles in membranes, including modulation of phospholipid packing density, separation of phospholipid headgroups and disruption of interactions between neighboring headgroups, alteration of membrane permeability behavior, and regulation of membrane-bound enzyme activities. Therefore, studies of the interactions between cholesterol and phospholipids and their consequences with respect to membrane structure and function have been the subject of intense scrutiny for more than three decades.^{4–7}

Much of the current understanding of the effects of cholesterol in membranes has come from studies of model bilayer membranes, which are formed by simply dispersing phospholipids, cholesterol, and other compounds in aqueous media. Since the composition of these aqueous dispersions is easily controlled, bilayers prepared from fully hydrated phospholipids have been used extensively in physicochemical studies. This review of the use of NMR for the study of phospholipid–sterol interactions places special emphasis on ²H NMR. The principal topic in this review is the use

of NMR to obtain information about the equilibrium phase behavior of cholesterol–phospholipid mixtures, as expressed in phase diagrams and measurements of the order of the hydrocarbon region of membranes. We also present here a brief review of selected NMR literature on methods employing several nuclei that has led to our current understanding of sterol–phospholipid interactions, together with an overview of differential interactions of cholesterol with a variety of phospholipid subclasses such as ester- and ether-linked phosphatidylcholines (PCs).

2 EARLY WORK ON CHOLESTEROL–PHOSPHOLIPID INTERACTIONS

Some of the earliest work on cholesterol–phospholipid mixtures in model bilayer membranes was carried out using X-ray diffraction and differential scanning calorimetry (DSC) techniques, which produced phase diagrams that were refined as discussed below.^{4,8} These studies led to the concept that cholesterol produces a state of ‘intermediate fluidity’ in a phospholipid by decreasing hydrocarbon chain motion in the liquid crystalline state and increasing the hydrocarbon chain motion in the gel state.⁴ These properties of bilayers were consistent with earlier observations in monolayers that showed that cholesterol ‘condensed’ phospholipids in which there was freedom of chain motion⁹ and expanded phospholipids in which chain motion was restricted.¹⁰ More precise DSC studies led to a partial phase diagram of the dipalmitoylphosphatidylcholine (DPPC)–cholesterol system,¹¹ and partitioning experiments with the spin probe Tempo (2,2,6,6-tetramethylpiperidine-*N*-oxyl) resulted in partial phase diagrams of dimyristoylphosphatidylcholine (DMPC)–DPPC mixtures with parts of the boundaries of the *L_α*, or liquid-disordered (*ld*) and liquid-ordered (*lo*), delineated.¹² Similarly, a partial phase diagram was constructed for DMPC–cholesterol mixtures which included the gel or solid-ordered (*so*), *ld*, and *lo* regions (see below).¹³

The first use of NMR to investigate phospholipid–cholesterol interactions was carried out by Chapman and Penkett,¹⁴ who used continuous wave ¹H NMR to show that cholesterol broadened the resonances of the fatty acyl chains and headgroup of egg PC bilayers above the phospholipid phase transition temperature. Similar information was obtained from other early ¹H and ¹³C NMR studies of various phospholipid–cholesterol mixtures.¹⁵ The first application of ²H NMR to the investigation of model membranes was a study of the effects of cholesterol and temperature on dual-chain perdeuterated DMPC-*d*₅₄ bilayers.¹⁶ Above the phase transition temperature (*T_m*), cholesterol caused the quadrupole splitting of the methylene deuterons to increase, indicative of increased order and reduced motion in the presence of cholesterol. Use of PCs and cholesterol, specifically deuterated at selected sites, provided a wealth of information about the PC–cholesterol system; for references to early ²H NMR studies, see Davis¹⁷ and Vist and Davis.¹⁸ Many of these studies suffered from the drawback that it was not possible to reproduce faithfully the ²H NMR lineshapes, particularly in the gel phase, with the pulsed Fourier transform methods then in use. The introduction of quadrupole echo Fourier transform NMR¹⁹ overcame

this problem and allowed essentially undistorted ^2H NMR spectra to be recorded and detailed phase diagrams to be produced. Application of this technique to examine order and dynamics in deuterated DMPC-cholesterol mixtures²⁰ and other bilayer-forming phospholipids (reviewed in Davis¹⁷) followed quickly. Proton magic angle sample spinning NMR has also been applied to the study of phospholipid-cholesterol interactions.²¹ Recently, ^2H NMR was used to carry out a comprehensive examination of molecular order and dynamics in DMPC-cholesterol mixtures.²²

3 REFINEMENT OF PHOSPHOLIPID-CHOLESTEROL NMR STUDIES

3.1 The Effect of Cholesterol on Phospholipid Acyl Chain Order

The ^2H NMR spectrum of a deuteron on the acyl chain of a phospholipid in the liquid crystalline state of a bilayer with random orientation is an axially symmetric Pake doublet. The sharp edges of the doublet arise from molecules undergoing reorientation about an axis that is perpendicular to the applied magnetic field. The quadrupolar splitting of these 90° edges is

$$\Delta\nu_Q = \frac{3}{4} \frac{e^2 q Q}{h} S_{\text{CD}} \quad (1)$$

where S_{CD} , the orientational order parameter of the carbon-deuterium bond, is given by

$$S_{\text{CD}} = \frac{1}{2} (3 \cos^2 \theta_{\text{CD}} - 1) \quad (2)$$

In equation (2), θ_{CD} is the angle between the carbon-deuterium bond and the applied magnetic field, and the average is over the motions of the bond. In the gel phase, the chains are more highly ordered, so their slower, asymmetric motion results in a broad spectrum with no sharp features. The ^2H NMR spectra of deuterated lipids have been reviewed in Davis.¹⁷

The ^2H NMR spectrum of perdeuterated phospholipids in the liquid crystalline phase of bilayers is a superposition of doublets with a range of splittings reflecting the decrease in orientational order toward the bilayer center. The effect of cholesterol on the chains is illustrated in Figure 1. Above T_m , which is about 38°C for DPPC- d_{62} , addition of cholesterol increases the doublet splittings, indicative of an increase in acyl chain order and bilayer thickness. Below T_m , the spectrum in the presence of cholesterol indicates that the chains are ordered but undergoing axially symmetric reorientation. The result is a superposition of axially symmetric doublets with large splittings.

Incorporation of DPPC- d_{62} (at 25 mol%) into undeuterated egg PC liposomes resulted in the appearance of a plateau region (which reflects the superposition of the quadrupole splittings of the seven or eight CD_2 groups nearest to the glycerol backbone) and a series of peaks for the more motionally disordered segments between the middle of the chain and the terminal CD_3 group.²³ Incorporation of cholesterol (at 50 mol%) increased the peak-to-peak quadrupole splittings by 75–140%, indicative of a more ordered system.

Figure 1 ^2H NMR spectra of DPPC- d_{62} in DPPC- d_{62} -cholesterol (chol) bilayers. Spectra were collected at 23.2 MHz using the quadrupole echo sequence with a pulse separation of $40\ \mu\text{s}$. (a) $x_{\text{chol}} = 0.035$, $T = 40^\circ\text{C}$; (b) $x_{\text{chol}} = 0.16$, $T = 40^\circ\text{C}$; (c) $x_{\text{chol}} = 0.285$, $T = 40^\circ\text{C}$; (d) $x_{\text{chol}} = 0.035$, $T = 35^\circ\text{C}$; (e) $x_{\text{chol}} = 0.16$, $T = 35^\circ\text{C}$; (f) $x_{\text{chol}} = 0.285$, $T = 35^\circ\text{C}$

3.2 The Effect of Analogs of Cholesterol on Phospholipid Acyl Chain Order

3.2.1 ^2H and ^{13}C NMR Studies of the Interaction of Epicholesterol (5-Cholesten-3 α -ol) with PC

NMR and other physical studies have shown that the molecular features required in a sterol for the ability to moderate the angular fluctuations of phospholipids in bilayers are a planar steroid nucleus, a 3β -hydroxy group, and a long apolar side chain at C-17. Deletion of any of these features results in failure of cholesterol to reduce membrane permeability, broaden the gel-to-liquid-crystalline phase transition, or reduce the mean molecular area of phospholipids in monolayers. Sterols with a planar α face interact principally by van der Waals interactions with the phospholipid acyl chains. Lanosterol, which lacks a planar α face since its 14α -methyl group protrudes from this surface, has considerably more mobility than cholesterol in PC vesicles as judged by ^{13}C NMR.²⁴

The relative mobilities of cholesterol and epicholesterol have also been compared in bilayers. The rotational freedom of cholesterol molecules in sonicated phospholipid vesicles can be estimated from spin-lattice relaxation (T_1) and linewidth ($\Delta\nu_{1/2}$) measurements of selected carbon resonances. A comparison of the rotational freedom of cholesterol and epicholesterol in egg PC vesicles was made by ^{13}C NMR as a function of temperature.²⁵ Below 32°C epicholesterol has a broad C-6 resonance of about the same linewidth as the C-6 nucleus of cholesterol, and both sterols have a similar effect on PC dynamics as estimated from their ability to cause similar broadening of the sn -1 carbon but not of the sn -3 carbon. At 41 – 42°C , however, the motion of epicholesterol is less restricted than that of cholesterol in egg PC vesicles, as judged by the observation of resonances from C-9 and C-14,17. These studies provide additional proof that the dynamics of component lipids are relevant to membrane function.

Models have been proposed to explain the molecular basis of the differential effects of epicholesterol and cholesterol on the packing of phospholipids in bilayers. Although both

sterols are oriented with the long axis normal to the bilayer surface, a collinear hydrogen bond may be formed with the 3β -hydroxy group of cholesterol and an acceptor such as one of the carbonyl oxygen atoms of the phospholipid;²⁶ alternatively, the 3β -hydroxy group of cholesterol may be more extensively hydrated than the 3α -hydroxy group of epicholesterol.²⁷ On the basis of ^2H NMR studies with specifically deuterated cholesterol and epicholesterol in DMPC or DMPC- d_{27} bilayers between 10 and 65 °C, a pronounced tilt of epicholesterol with respect to the bilayer normal was evident at physiological temperatures.²⁸ Furthermore, the iso-octyl side chain of cholesterol was found to be as ordered as the steroid nucleus. The quadrupolar splittings of epicholesterol and cholesterol deuterated at C-3 in DPPC bilayers suggested that the angle of tilt of the sterol nucleus relative to the bilayer normal is different in the two sterols.²⁹ Cholesterol was estimated to be inclined at an angle of 16–19° at 24 °C and 60 °C, which is similar to the tilt of the fatty acyl chains in bilayers; thus, the steroid nucleus and the phospholipid fatty acyl chains have a nearly parallel alignment, with the 3β -hydroxy group projecting toward the water and fully accessible for hydrogen bonding. In contrast, the steroid nucleus of epicholesterol was proposed to lie nonparallel to the phospholipid fatty acyl chains at 24 °C. The 3α -hydroxy group was postulated to lie essentially perpendicular to the bilayer normal, accessible to interaction with water, but positioned at an angle that increases the distance between the steroid nucleus and fatty acyl chains, thus diminishing the extent of lipid–lipid interactions and perturbing the packing of the lipid chains. These studies make clear the reason why epicholesterol is not a naturally occurring membrane component; its presence would destabilize bilayers by disturbing close packing of lipid chains.

3.2.2 ^2H NMR Studies of the Interaction of Terpene Alcohols ('Cholesterol Ancestors') with PC

Many polyterpenoid 'ancestors' of cholesterol, although they resemble cholesterol in their rigidity, overall cylindrical shape, and amphiphilic character, generally fail to increase the acyl chain order of phospholipids in fluid phase oriented multilayers, as probed by the increase in mean order parameter using single chain perdeuterated phospholipids such as DMPC- d_{27} and DPPC- d_{31} .³⁰ Thus the molecular dimensions of cholesterol have apparently evolved in a manner that permits this sterol to play an important role in modulating membrane structure, and this sterol became ubiquitous in most eukaryotic cell membranes. Incorporation of cholesterol at 30 mol% increases the order parameter of the plateau region and terminal methyl region by 78% and 130%, respectively.³¹ The extent to which a cholesterol surrogate has the capacity to increase the mean order parameter of oriented bilayers represents a measure of its resemblance to cholesterol.

3.3 Interaction of Cholesterol with Sphingomyelin

There is considerable evidence that the lateral packing density of cholesterol with sphingomyelin is higher than that with PCs (for references, see Bittman³²). However, ^{13}C NMR studies of [4- ^{13}C]cholesterol did not reveal a significant difference in the rotational freedom of cholesterol molecules

in PC and sphingomyelin sonicated vesicles, as estimated by $\Delta\nu_{1/2}$ and T_1 measurements.³³ There is substantial evidence that sphingomyelin bilayers are packed more tightly than PC bilayers of similar degree of acyl saturation. Early ^2H NMR studies of unsonicated bilayers showed that a semisynthetic sphingomyelin labeled with deuterium at C-10 of the amide-linked chain had significantly higher quadrupole splitting ($\Delta\nu_Q$) than DPPC labeled with deuterium at C-10 of the *sn*-2 palmitoyl chain.³⁴ More detailed studies of this system are required with specifically labeled, chemically defined sphingomyelins in order to examine whether the mode of packing of cholesterol differs in sphingomyelin and PC bilayers.

3.4 Interaction of Cholesterol with Ether-Linked Phosphocholines

3.4.1 ^1H NMR Studies with Plasmenylcholine and PC Vesicles

It is of interest to examine the possibility that cholesterol modulates the motional characteristics of the major mammalian choline glycerophospholipids' subclasses in a differential manner. Proton spin–lattice relaxation times and apparent activation energies of T_1 relaxation times for vinyl and bisallylic methylene protons in liquid crystalline bilayers of a diacyl-PC (1-palmitoyl-2-arachidonoyl-3-PC) were higher than that of a plasmenylcholine, 1-*O*-(*Z*)-hexadec-1'-enyl-2-arachidonoyl-3-PC.³⁵ Incorporation of cholesterol resulted in substantial decreases in the proton spin–lattice (T_1) relaxation times in the interior regions of plasmenylcholine bilayers, and this decrease was larger than that in PC bilayers. On the other hand, the T_1 values of the choline methylene protons of plasmenylcholine bilayers were increased on introduction of cholesterol, and this increase was larger than that found in diacyl-PC bilayers.

Although ^2H and ^{13}C NMR studies have shown that polar headgroup motion of phospholipids in multilamellar vesicles is not significantly altered by incorporation of cholesterol,^{13,36} the spin–spin relaxation times (T_2) of CH_2N and $\text{N}-\text{CH}_3$ of both PC and plasmenylcholine sonicated vesicles were decreased by cholesterol (at 30 mol%); also, the T_2 values of the bis-allylic protons of arachidonic acid in PC or plasmenylcholine vesicles were decreased by cholesterol (at 30 mol%).³⁷ These proton spin–spin relaxation time measurements indicate that introduction of cholesterol results in slower motion of the polar headgroup of plasmenylcholine and PC vesicles. Since plasmenylcholine lacks an ester linkage at the *sn*-1 position, yet still has its motional properties altered by cholesterol, these results suggest that hydrogen bonding to an *sn*-1 carbonyl group of diacyl-PC is not required for interaction of phospholipids with cholesterol.

3.4.2 ^{13}C NMR Studies of Saturated Ether-PC and Ester-PC Vesicles

The conclusion stated above is consistent with previous ^{13}C NMR studies of cholesterol enriched with ^{13}C at the 4-position, in which ^{13}C NMR relaxation measurements indicated that no significant relocation of the 4- ^{13}C atom of cholesterol took place when a methylene group was substituted for a carbonyl

group in PC sonicated vesicles.³⁸ The apparent spin-spin relaxation time $T_2 [= (\pi \cdot \Delta \nu_{1/2})^{-1}]$, which reflects mainly slower motions involving reorientation of local segments, for the $4\text{-}^{13}\text{C}$ atom of cholesterol was shorter in bilayers prepared with 1-ester-2-ether-PC or 1,2-diether-PC than in those prepared with 1,2-diester-PC. Thus, the presence of an *sn*-2 *O*-alkyl linkage in PC rather than an *sn*-2 ester linkage appears to result in a relatively restricted motion of cholesterol (present at 10 mol%). In a diester-PC, the arrangement of the *sn*-1 and *sn*-2 chains is different near the lipid-water interface; the ester linkage at *sn*-2 lies at the interface, whereas the *sn*-1 ester linkage penetrates into the bilayer. In PCs having an *sn*-2 *O*-alkyl linkage, the absence of a bend results in tighter packing of PC molecules in this region of the membrane interface, which is reflected in the shorter apparent T_2 values for $[4\text{-}^{13}\text{C}]$ cholesterol in dihexadecyl- and 1-palmitoyl-2-*O*-hexadecyl-PC vesicles. This difference in lipid packing property does not require that formation of a hydrogen bond be postulated between cholesterol and the phospholipid. Indeed, no evidence for such a hydrogen bond was found in recent ^2H NMR studies of 3- $[^2\text{H}]$ -cholesterol in DMPC vesicles.³⁹ However, evidence for a putative hydrogen bond between the 3β -hydroxy group of cholesterol and the *sn*-2 carbonyl of DPPC has been suggested from a high-frequency shift in the ^{13}C NMR spectrum of DPPC carbonyl carbon atoms in the presence of cholesterol.^{40,41}

3.5 Use of Spectral Subtraction for Phase Diagram Determination

Many studies have been directed toward the refinement of phase diagrams of a variety of phospholipid-cholesterol systems by application of a wide range of physical techniques (see, for example, references cited in Vist and Davis¹⁸ and Blume and Griffin⁴²).

In excess water, a system containing two bilayer-forming components can be treated as a binary mixture. It can be shown that along a line of constant temperature in a binary phase diagram, regions corresponding to different homogeneous phases must be separated by regions in which the free energy of the system is lowered by separation into coexisting domains of the adjacent homogeneous phases. One approach to determining the boundaries of such regions of two-phase coexistence is to scan the temperature through the two-phase region, while observing some property that is sensitive to the thermodynamic phase of the sample, such as excess specific heat in a DSC experiment or lineshape in an NMR experiment. When carried out for a series of sample concentrations, this type of experiment indicates the upper and lower temperature limits of two-phase coexistence for a particular composition.

In order to describe the way in which spectral differences are used in phase diagram studies, we consider here a two-component bilayer system with a temperature and composition that falls within a region of two-phase coexistence in the binary phase diagram. We will use x to denote the mole fraction of component 2 in the bilayer. For the purpose of this discussion, we will take the coexisting phases to be a phase G with a lower concentration of component 2 and a phase F , which is richer in component 2. If, at a particular temperature T , the composition x falls within the two-phase region, the mixture will separate into domains of G and F , with compositions that

correspond to the points at which an isotherm at temperature T intersects the boundaries of the two-phase region. These points are referred to as endpoints. For the example described here, the gel-phase boundary composition at temperature T is labeled $x_G(T)$, and the fluid-phase boundary composition is labeled $x_F(T)$. If component 2 lowers the $G \rightarrow F$ transition temperature, then we have $x_F(T) > x_G(T)$. The partitioning of the sample between the coexisting phases is determined by the lever rule. For example, the fraction of the sample in the F phase will be given by

$$f_F(x, T) = \frac{x - x_G(T)}{x_F(T) - x_G(T)} \quad (3)$$

Consider the situation where one of the components is deuterated. We will take component 1 to be the labeled component. The endpoint concentrations can be determined if exchange between domains of the coexisting phases is slow on the ^2H NMR timescale.⁴³ Under these circumstances, the observed spectrum $S(x)$ for a sample of composition x in the two-phase coexistence region, at a particular temperature, will be a superposition of spectra S_G and S_F , corresponding to the endpoint compositions at that temperature. If $S(x)$, S_G , and S_F are normalized to a constant area, then the observed spectrum is given by

$$S(x) = \frac{(1 - x_G)(x - x_F)}{(1 - x)(x_G - x_F)} S_G + \frac{(1 - x_F)(x_G - x)}{(1 - x)(x_G - x_F)} S_F \quad (4)$$

The factor multiplying S_G (S_F) in equation (4) is the number of labeled molecules in phase G (F) divided by the total number of labeled molecules in the sample. Under some circumstances, it may be necessary to apply a correction to account for different transverse relaxation rates in the coexisting phases.

Consider two spectra, $S(x_A)$ and $S(x_B)$, obtained for sample compositions x_A and x_B on the same tie line within a two-phase region. They should consist of the same pair of endpoint spectra superimposed in differing proportions. If $x_A > x_B$, then $S(x_A)$ will contain a higher proportion of S_G than will $S(x_B)$. By subtracting one observed spectrum from the other, one can obtain a spectrum that is exclusively characteristic of one or the other endpoints. K is defined as the fraction of $S(x_B)$ that must be subtracted from $S(x_A)$ to yield S_G . Similarly, K' is the fraction of $S(x_A)$ that must be subtracted from $S(x_B)$ to yield S_F . The endpoint compositions are given by

$$x_G = \frac{x_A(1 - x_B) - Kx_B(1 - x_A)}{(1 - x_B) - K(1 - x_A)} \quad (5)$$

and

$$x_F = \frac{x_B(1 - x_A) - K'y'A(1 - x_B)}{(1 - x_A) - K'(1 - x_B)} \quad (6)$$

For locating phase boundaries, spectral subtraction complements other methods in which properties are observed as sample temperatures are scanned through the region of interest. If several spectra are available along a tie line, a consistent result obtained from a series of different pairwise subtractions provides evidence that the system obeys the lever rule and that the observed spectral changes do indeed reflect two-phase coexistence. Scanning techniques such as DSC depend on the

identification of a threshold temperature at which a property, such as excess heat capacity, exhibits departures from baseline behavior. As such, they are sensitive to the way in which the baseline is extrapolated into the coexistence temperature range. It is significant that the spectral difference approach is based on equilibrium partitioning of the sample.

In practice, K or K' is varied until features characteristic of one or the other coexisting phases are eliminated. The ease with which the appropriate values of K and K' are assigned is very sensitive to the distinctness of the spectra corresponding to the two endpoints. The DPPC- d_{62} -cholesterol system presented a particular challenge to the spectral subtraction technique. Figure 2 shows the form of the phase diagram obtained by Vist and Davis.¹⁸ The labels *ld* and *so* correspond to the liquid-disordered (or liquid crystal) and solid-ordered (or gel) phases, respectively. The *ld*-*so* coexistence region below 7.5 mol% cholesterol was less than 1 °C wide. The nearly horizontal boundaries of this region were determined by inspection of spectra for samples with cholesterol concentration below 7.5 mol% under the assumption that spectral subtraction in this region would be overly sensitive to uncertainty in the sample temperature. Figures 1(a) and 1(d) are characteristic of the *ld* and *so* spectra above and below this two-phase region. The spectra in the *lo* phase beyond about 20 mol%, which Vist and Davis¹⁸ labeled the ' β ' phase, are axially symmetric but with a greater

Figure 2 A schematic drawing of the PC-cholesterol phase diagrams. For DPPC- d_{62} , the three-phase line (separating *so* + *lo* from *ld* + *lo*) is at 37 °C and extends from about 7 mol% to 20 mol% cholesterol.¹⁸ For POPC- d_{31} -cholesterol, the three-phase line is at about -7 °C and extends from 7 mol% to about 20 mol% cholesterol.⁴⁵ For stearoyl-elaidoyl-PC- d_{35} -cholesterol, the three-phase line is at about 31 °C and extends from about 10 to 25 mol% cholesterol.⁴⁶ *ld* is the liquid-disordered phase (also called liquid crystal or L_α). *lo* is the liquid-ordered phase (called β by Vist and Davis¹⁸), *so* is the solid-ordered phase (also called gel or L_β). (Adapted from Vist and Davis¹⁸)

average splitting than in the liquid crystalline phase. Figures 1(c) and 1(f) are characteristic of this phase. Within the *ld*-*lo* coexistence region, there was evidence that fast exchange between domains of the two phases caused averaging of the spectra, and spectral differences again were not used. The boundary between *ld* and the *ld*-*lo* coexistence region was determined from DSC studies. Figure 1(b) corresponds to a point inside the two-phase region close to the boundary. Below 20 mol% cholesterol, the lower boundary of this region is a three-phase line at which the *so* phase melts into the *ld* phase. This line was primarily identified from a sharp transition observed calorimetrically. The boundary between the *ld*-*lo* coexistence region and the *lo* region was assigned at the point where the sharp doublets of the *lo* phase broadened as the sample temperature was increased. This was taken to indicate the onset of spectral averaging due to fast exchange with domains of liquid crystal. Determining the exact location of this boundary remains somewhat problematic.

Within the *so*-*lo* region, spectral subtraction provided important evidence of predominantly vertical boundaries. Figure 1(e) is characteristic of spectra in this region. Such spectra are not obvious superpositions of spectra from two coexisting phases. However, spectral subtraction did give rise to endpoints that were characteristic of the *so* phase and axially symmetric endpoint spectra with large quadrupole splittings that were identified as arising from the *lo* phase. That these were indeed true endpoint spectra was confirmed by comparison with spectra obtained from samples having cholesterol concentrations close to the endpoint concentrations determined by spectral subtraction.

The doublet with the smallest splitting in the axially symmetric spectra arises from the methyl deuterons at the ends of the acyl chains. At high cholesterol concentration, the methyl doublet was split, indicating a slight difference in ordering of the two chains near the bilayer center (see Figure 1).¹⁸ The temperature dependence of the splitting was examined,⁴⁴ and a correspondence was noted between the temperature at which the inequivalence of the methyl deuterons disappears and the boundary of the *ld*-*lo* coexistence region reported by Vist and Davis.¹⁸ Partial orientation of DPPC- d_{62} vesicles containing 25 mol% cholesterol was found between 36 and 42 °C, which was attributed to a change in the mechanical properties of the bilayer. The temperature dependence of these effects in the *lo* phase may reflect a reorganization of cholesterol from a position near the bilayer center to one closer to the headgroup region with increasing temperature.

Spectral differences were also used to determine the phase diagrams of mixtures of cholesterol with two unsaturated PCs.⁴⁵ Although the phase diagrams were shifted to lower temperatures, in accordance with the T_m values of the phospholipids, remarkable similarities with the DPPC-cholesterol phase diagrams are apparent. A universal shape for the PC-cholesterol phase diagram was postulated, and it was suggested that the β or *lo* phase is probably common to cholesterol-rich biological membranes. No attempt was made to define the *ld*-*lo* coexistence region. Recently, the comparison was extended to mixtures of stearoyl-elaidoyl-PC and cholesterol, which were also found to resemble the DPPC-cholesterol phase diagram.⁴⁶ In each binary mixture, the shift on temperature of the three-phase line, relative to that for DPPC-cholesterol, is approximately the same as the shift in the pure phospholipid transition temperature relative to

that for DPPC. Theoretical efforts to model the DPPC phase diagram have been reviewed.^{47,48}

4 OTHER RECENT PHOSPHOLIPID-CHOLESTEROL PHASE DIAGRAM STUDIES

The determination of phospholipid-cholesterol phase diagrams by using neutron scattering has been reviewed.⁴⁹ Electron spin resonance studies generated phospholipid-cholesterol phase diagrams in which a phase boundary was detected that appears to correspond to the boundary between the *ld-lo* coexistence region and the *lo* region beyond 20 mol% cholesterol.⁵⁰

The phospholipid-cholesterol phase diagram has also been studied by Griffin and co-workers using a variety of techniques, including ¹³C NMR. A region of two-phase coexistence below *T_m* was found in the phase diagram for dipalmitoylphosphatidylethanolamine-cholesterol mixtures by using ²H and ¹³C NMR.⁴² In a similar study with distearoyl-PC (DSPC)-cholesterol and DPPC-cholesterol systems, the ¹³C NMR spectrum of the *sn*-2 carbonyl was found to be an axially symmetric powder pattern with a width of about 100 ppm in the gel phase.^{42,51} In the liquid crystalline phase, the spectrum is a narrow line (5–10 ppm in width), suggestive of isotropic motion. This behavior is attributed to a conformational change in which the unique axis of the chemical shift tensor orients close to the magic angle. In the *P_{β'}* phase, a superposition of the powder pattern and narrow line spectra is seen. As cholesterol is added, the temperature at which the narrow component first appears is lowered. Where the narrow and powder pattern components are superimposed, the narrow component is broadened. The presence of the narrow and powder pattern spectral components together was taken to indicate the coexistence of a cholesterol-rich phase (*LG₁* or *lo*) and the gel phase (*L_β* or *so*). The broadening of the narrow component was simulated by assuming exchange between domains of the two phases. In this way, estimates of domain size have been obtained. The boundary of the *LG₁* or *lo* region above the temperature of the three-phase line was determined by ²H NMR. The boundary of the *lo* region below the temperature of the three-phase line was found to be shifted to higher cholesterol concentration in mixtures containing the longer chain DSPC compared with DPPC.

The boundary of the DPPC-cholesterol *so-lo* region determined by ²H NMR appears to be rather different from that determined by ¹³C NMR. Carbon-13 NMR measurements indicated that the boundaries of this region curve toward higher cholesterol concentration as the temperature is lowered,⁵¹ whereas ²H NMR measurements showed the corresponding boundaries to be nearly vertical.¹⁸ Similar results were obtained in mixtures of cholesterol with some unsaturated phospholipids.^{45,46} However, the temperature ranges over which these boundaries have been determined by ²H NMR are limited.⁵¹ Whether there is really a discrepancy between the findings of the two techniques regarding these boundaries is not clear at this time.

A variety of techniques, including ²H NMR, electron spin resonance, and fluorescence recovery after photobleaching, have been applied to the construction of phospholipid-cholesterol phase diagrams⁵² that are qualitatively similar to the one reported by Vist and Davis.¹⁸ Based

on ²H NMR studies of bilayer thickness in a series of PCs with increasing chain length, it was suggested that cholesterol spans the bilayer in the *ld* phase and that, with increasing cholesterol concentration and increasing order, the bilayer becomes partially interdigitated in the *lo* phase.⁵³ The fluid phase immiscibility represented by the *ld-lo* region was attributed to this behavior.

5 CONCLUDING REMARKS

What are the implications of these findings for biological membranes? There are common features for each of the lipid-cholesterol phase diagrams, with three phases, *so*, *lo*, and *ld*, plus the corresponding two-phase regions appearing for each phospholipid-cholesterol combination. The phase boundaries show similar, although not identical, properties with respect to cholesterol concentration, with their positions being dependent on the specific phospholipid involved.

At their physiological temperature(s), the lipids of most membranes will be above *T_m* and above the three phase lines in the phase diagrams. Plasma membranes, therefore, will be in the *lo* or, at elevated temperatures, in the *ld* state. Under equilibrium conditions, these are continuous phases, although interaction energies might vary between cholesterol and individual, specific phospholipids. (Indeed, such comparisons should be made with full knowledge of the phase diagrams, so that cholesterol-phospholipid interactions in comparable phases can be compared.) Subcellular membranes and other membranes having low cholesterol content, on the other hand, while possibly being in the phases just mentioned, might also exist in the *ld-lo* two-phase region above the three-phase line. Thus, cholesterol-enriched and cholesterol-poor regions could coexist in membranes, and these domains might have important consequences for insertion and regionalization of proteins, and for modulation of protein functions.

1 INTRODUCTION

Solid state NMR spectroscopy is one of the premier methods for characterizing protein dynamics. It is used primarily to describe the intramolecular motions of proteins that are immobilized as part of supramolecular structures in solution, such as membrane or virus particles, or in crystalline samples. Although many different experiments and calculations reflect the internal motions in proteins, it is generally quite difficult to extract detailed information about these motions. By contrast, the effects of motional averaging on the lineshapes of solid state NMR spectra are so clear cut that their analysis has provided a very large proportion of the definitive information currently available about protein dynamics.

Spectral parameters from the nuclear spin interactions operative in both solution NMR and solid state NMR experiments are strongly affected by motion; however solid state NMR experiments have the advantages of avoiding the influences of overall reorientation and analyzing the effects of motional averaging on powder pattern lineshapes. Since the proteins themselves are immobilized by their environments, motion associated with specific backbone or side-chain sites can be readily identified. For the most part, solid state NMR studies of molecular dynamics rely on the analysis of powder patterns by comparing the experimental lineshapes with those calculated for static sites affected by specific models of motional averaging, although relaxation parameters can be analyzed in combination with the lineshapes to determine the actual frequencies of the motions. These studies typically require isotopic labeling of the protein with ^2H , ^{13}C , or ^{15}N .

An important benefit of solid state NMR studies is that the structure and dynamics of proteins can be considered in concert. Both orientation and distance measurements are feasible with solid state NMR experiments, and these results can be used to determine the three-dimensional structures of proteins. Of course, the results of the NMR dynamics studies are complementary to the structural information also derived from X-ray crystallography and solution NMR spectroscopy. The backbone and side-chain motions of individual residues are of considerable interest because they have a profound effect on the properties and functions of proteins, especially

the structural and membrane proteins where solid state NMR spectroscopy finds its greatest applicability.

2 SOLID STATE NMR SPECTROSCOPY

The precise nature of the influence of molecular motion on spectral parameters, especially powder pattern lineshapes, depends on the spin interactions that are present at the site of interest, the frequencies, amplitudes, and directions of local and global motions, and experimental parameters such as the frequencies of the resonances and the amplitudes and timings of the irradiations. There is a comprehensive review on the subject of NMR studies of dynamics and it provides the necessary physical and mathematical detail for understanding the roles of motion in solid state NMR spectroscopy.¹ There are also reviews on the applications of solid state NMR spectroscopy to protein dynamics.^{2,3}

The solid state NMR approach to studying molecular dynamics that is most successful relies on the fundamental concept of dilute spins to provide the necessary isolation of the spin interactions. The spin- $\frac{1}{2}$ nuclei of ^{13}C and ^{15}N are available in isotopically enriched sites in proteins. Although these spins interact strongly with the abundant ^1H spins, which can usually be decoupled with strong enough irradiation, they do not interact among themselves; therefore, the spectral parameters available for the analysis of motional averaging are heteronuclear dipolar couplings and chemical shift anisotropy. Deuterium with spin 1 is widely used in solid state NMR studies of molecular dynamics because its lineshapes are dominated by the effects of the nuclear quadrupole interaction, and ^2H labeling can be placed in backbone and side-chain sites.

In polycrystalline or unoriented samples, where the proteins do not undergo rapid overall reorientation, powder pattern lineshapes like those in Figure 1 are obtained.² The absence of motion in a molecular site must always be defined with respect to a frequency determined by the observed spectral parameter from the dominant spin interactions. Static powder pattern lineshapes are calculated from the principal values of the tensor that describes the spin interaction by taking into account the probability density of all orientations of the tensor with respect to the applied magnetic field. The frequency breadth of a powder pattern reflects the total spectral range for the resonance frequencies possible for the spin interactions at a particular site, since all possible angles are present in a powder. It is this breadth that determines the lower limit for the frequencies of motions that can influence the powder pattern lineshape.

Figure 1 Calculated static powder patterns for an aromatic carbon site. (a) ^{13}C chemical shift anisotropy. (b) ^{13}C - ^1H heteronuclear dipolar coupling. (c) ^2H quadrupolar coupling. (Reproduced by permission from Opella.²)

Figure 1 presents calculated powder patterns for three spin interactions that can be arranged to be present through isotopic labeling at an aromatic carbon site with a bonded hydrogen. The ^{13}C chemical shift powder pattern from an aromatic carbon is clearly nonaxially symmetric; the ^{13}C - ^1H dipolar powder pattern is axially symmetric; and the ^2H quadrupolar powder pattern is nearly axially symmetric. These spectra are displayed on a constant frequency scale in Figure 1 to demonstrate the range of frequencies to which the different spectral parameters are sensitive. For example, the chemical shift powder pattern is averaged by motions substantially slower than those required to average the heteronuclear dipolar and quadrupole powder patterns.

In addition to the frequencies of the motions, the lineshapes are affected by their amplitudes, directions, and other characteristics. In order to understand the influences of these factors, specific models of motions must be considered because of the intimate relationships among molecular sites, spin interactions, and the motions. There are substantial differences between how slow, large amplitude motions and rapid, small amplitude motions affect lineshapes; examples of both are seen in proteins.

3 BACKBONE SITES IN PROTEINS

The initial step in the investigation of a protein is to find out if the entire polypeptide chain is immobile. This information, by itself, is highly suggestive about general aspects of the architecture of the protein, since mobile residues do not participate in the secondary structure of the protein. This is particularly relevant for membrane proteins which characteristically have mobile loops and termini and rigid, structured helical regions. Backbone dynamics are characterized most directly by observing powder pattern lineshapes from labeled sites in unoriented samples and comparing their shape and breadth with those from rigid polycrystalline samples. Residues that undergo large-amplitude motions more often than the frequency breadth of the powder pattern are readily recognized because they have narrow resonance lines at the average, isotropic frequency. The spectra in Figure 2 demonstrate that it is possible to observe narrow, isotropic resonance intensity from the mobile sites superimposed on the broad powder pattern lineshape from the structured sites in a membrane protein.⁴ The narrow resonance intensity arises from the mobile sites near the N- and C-termini, although most of the residues of the membrane-bound form of the protein are rigidly held in structured helical regions of the protein.

As shown in Figure 2, ^{15}N -labeled protein samples are very useful in describing the dynamics of proteins. However since the amide tensor in the backbone sites is nearly axially symmetric with the parallel component along the helical axis, it is necessary to observe powder patterns from other sites in order to establish if rotation about an axis coincident with transmembrane helices in the bilayer is occurring. The indole nitrogen of tryptophan side chains is ideal for this, enabling this site to be used to monitor the global motion of the protein since the bulky, asymmetric side chain is rigidly held within the framework of the protein. The results for the membrane-bound form of fd coat protein are shown in Figure 3.⁵ The data from ^{15}N -labeled gramicidin in bilayers are quite different;

Figure 2 Experimental solid state ^{15}N NMR spectra of the membrane-bound form of fd coat protein in lipid bilayers. (a) Uniformly ^{15}N labeled. (b) Selectively ^{15}N glycine-labeled (four residues). (c) Selectively ^{15}N leucine-labeled (two residues). (d) Selectively ^{15}N Phe-labeled (three residues). (e) Selectively ^{15}N lysine-labeled (five residues). (Reproduced by permission from Bogusky et al.⁴)

although at low temperatures the peptide is immobile, it rapidly rotates at higher temperatures in bilayers.⁶ Experiments with other nuclei have confirmed these same results for gramicidin.⁷ Global molecular reorientation about a single axis has also been observed for Pf1 virus particles⁸ and bacteriorhodopsin in bilayers.⁹ In addition to the global motions and large-amplitude local motions, it is possible to use solid state NMR to describe smaller fluctuations through relaxation measurements.¹⁰

The backbone dynamics of several membrane proteins have been analyzed in detail by solid state NMR experiments.^{12–15} Dynamics studies of bacteriorhodopsin in particular have utilized spectra from both backbone and side-chain sites to monitor the motions of the backbone.^{16–19} Deuterium NMR spectra of many labeled sites show narrow isotropic resonance intensity superimposed on broad powder patterns,²⁰ which is typically the case for membrane proteins. The results have been interpreted in terms of structural models of bacteriorhodopsin where the mobile residues are most likely associated with the mobile C-terminus or interhelical loops.^{21,22}

4 AROMATIC SIDE CHAINS

The motions of the aromatic amino acid side chains have received a great deal of attention in all studies of

Figure 3 ^{15}N solid state NMR spectra of specifically indole-labeled Trp fd coat protein in lipid bilayers. (Reproduced by permission from Leo et al.¹¹)

protein dynamics. Not only are these residues important to the structure of the molecules, but also their bulk suggests that their individual motions must influence a substantial number of other residues. Phenylalanine and tyrosine rings have C_2 symmetry and an obvious path for internal motion, the C^β – C^γ bond axis. In principle, there are two limiting cases for reorientation of the rings around this axis: (1) jumps (or ring flips) between two indistinguishable sites, where the residence times are long compared with the transit times; and (2) diffusional rotation, where the rings are continuously moving about the bond axis. While all of the spin interactions present in the ring can be used in these studies, the vast majority of work has utilized ^2H quadrupole powder patterns to provide the experimental data.^{18,23–25} The calculated powder patterns shown in Figure 4 vary strongly with the types of motion.

fd is a filamentous bacteriophage consisting of about 3000 copies of its major coat protein surrounding its DNA. The virus and its coat protein are immobile on all NMR timescales analyzed. The coat protein is small, with two tyrosine residues. The lineshape of the ^2H NMR spectrum of [^2H]tyrosine (Tyr)-labeled fd virus is very similar in appearance to that calculated for the flip-averaged rings sites.²³ The protein has three phenylalanine (Phe) residues and the ^2H NMR spectrum of [^2H]Phe-labeled fd is a superposition of two different powder patterns. The inner pattern is from the δ and ϵ bonds undergoing rapid 180° ring flips; the lineshape is very similar to those observed for the Tyr-labeled sample and calculated for the flip-averaged static spectrum. The C–D bonds of the Phe rings contribute the outer discontinuities as a static powder pattern, because these deuterons are unaffected by reorientation about the C^β – C^γ bond axis.²⁴ The lineshape of the [^2H]Phe-labeled ^2H NMR spectrum demonstrates that these rings also flip rapidly. The observed frequencies in the powder patterns are reduced slightly from those anticipated for a rigid ring only undergoing flips, indicating the presence of some small-amplitude motions. The ^2H NMR powder pattern from the single tryptophan (Trp) residue shows its side chain to be tightly constrained within the protein.

Solid state NMR studies on peptides and proteins lead to some general conclusions about the dynamics of aromatic side chains. In the cases examined Trp rings are rigid on NMR

Figure 4 Solid state ^2H NMR spectra. (a), (b), and (c) are experimental spectra from selectively ^2H -labeled aromatic residues in fd bacteriophage. (d), (e), and (f) are calculated spectra for rigid C–D bonds subject to defined motional averaging. (a) Experimental spectrum from the one labeled tryptophan. (b) Experimental spectrum from the three labeled phenylalanines. (c) Experimental spectrum from the two labeled tyrosines. (Reproduced by permission from Gall et al.²³)

timescales, whereas many Tyr and Phe rings undergo two-site 180° hop motions. The aromatic side chains undergo both large-amplitude jump motions and small-amplitude librations in a well-defined manner. The conclusion based on the solid state NMR data is that the proteins in these side chains are both highly ordered and very mobile.

5 ALIPHATIC SIDE CHAINS

Most of the attention in solid state NMR studies of aliphatic side chains in proteins has been focused on CD_3 -labeled sites. Both lineshapes and relaxation parameters can

Figure 5 Comparison of experimental and calculated spectra for selectively CD_3 -labeled fd virus samples. Leu = leucine, Met = methionine, Thr = threonine, Val = valine. (Reproduced by permission from Colnago et al.⁵)

be analyzed. At temperatures of interest for proteins the lineshapes of deuterated methyl groups are axially symmetric powder patterns that are significantly reduced in breadth from a static pattern.^{26,27} Since jumps between three or more equivalent sites and diffusional rotation affect powder pattern lineshapes in the same way, the characteristic features of the spectra are indicative of only the angles of intramolecular motion. The facile reorientation of CD_3 groups about their C_3 axis has been extensively studied in crystalline amino acids and peptides, as well as proteins.^{5,11,17,19,28,29} It is relatively easy to place deuterated methyl groups in desired locations through synthesis or biosynthetic incorporation, and they have favorable properties for analysis.

The effects of the motional averaging on methyl groups have been observed in ^2H NMR experiments in many different amino acid side chains in peptides and proteins.^{5,11} Figure 5 compares calculated ^2H NMR powder patterns characteristic of the methyl group motions actually observed in proteins. All methyl groups undergo rapid reorientation about the C_3 symmetry axis. In addition, many aliphatic side chains undergo rapid jump motions about tetrahedral or near-tetrahedral carbon sites. The deuterium powder pattern lineshapes resulting from two-site jump motions on top of the C_3 axis methyl group reorientation can be calculated by standard methods as two-site 'fast-exchange' processes consisting of jumps between two equally populated positions. This was first demonstrated for leucine residues in collagen,²⁹ and subsequently in a variety of proteins. Of course, large-amplitude motions that occur in all directions result in isotropic averaging of the powder pattern lineshapes to single line resonances that occur at the central frequency for the interaction. Because of the limitations imposed by the side chains, the C–D groups can undergo isotropic reorientation only if the backbone at those residues undergoes isotropic reorientation.

6 SUMMARY

The methods for solid state NMR studies of protein dynamics are well developed, especially with regard to the

observation and analysis of motionally averaged powder pattern lineshapes of unoriented or polycrystalline samples. In large part, the success of the applications depends on the placement of isotopic labels in selected locations.

The main conclusion from solid state NMR studies of proteins is that their dynamics fall into three distinct categories. Sites that do not have large-amplitude motions, which occur frequently compared with the timescale of the spectral parameter measured, are categorized as 'rigid' or 'immobile', even if they have small-amplitude rapid motions that result in slight reductions of the parameters compared with static values. Some sites, especially in side chains, undergo large-amplitude jumps between several conformations with residence times that are long compared with the transit times between conformations. In addition, there are mobile sites that undergo rapid reorientation in many directions that are, by definition, unstructured.

Relaxation measurements can provide quantitative information about rates of motion. However, there are many variables that influence the interpretation of these results, and this limits the certainty of the conclusions about the amplitudes and directions of motions. Indeed, there is a tendency to reduce the detail by resorting to an order parameter analysis in order to increase the reliability of the interpretations. Optical and other methods of studying dynamics have even less detail and certainty.

Solid state NMR spectroscopy gives definitive descriptions of the most important backbone and side-chain motions of proteins. The combination of detail concerning the directions, amplitudes, and types of motions with the reliability of lineshape analysis makes this a very powerful approach for the analysis of the time-dependent behavior of proteins.

1 INTRODUCTION

Interest in selective relaxation experiments was aroused when it emerged that it was possible to interpret experimental selective relaxation parameters in terms of different relaxation contributions. Considering the dipole–dipole interaction between $I = \frac{1}{2}$ nuclei as the dominant relaxation contribution of biomolecules in solution, selective relaxation experiments can be used to calculate both selective ‘cross-relaxation’ rates σ_{ij} and individual, direct self-relaxation rates ρ_i . The observation of specific dipolar connectivities can provide useful information on several aspects of the chemical behavior of biomolecules, especially molecular structures and organization, solution dynamics, and biomolecular interactions.

2 SELECTIVE PULSE EXCITATION

Any selective relaxation experiment is performed with a specific pulse sequence which contains at least one selective excitation period. An ideal selective pulse should have the following features:^{1,2}

1. good frequency selectivity (i.e. uniform excitation of a limited spectral region);
2. short duration (to avoid effects such as relaxation, chemical shift, and coupling evolution during the pulse);
3. uniform phase behavior of the magnetization.

Several approaches, recently reviewed,^{1–3} have been developed, to generate excitation profiles to yield selective perturbation, starting from the pioneering work of Alexander.⁴ The pulse sequences proposed for selective excitation can be regarded as belonging to the following categories:

1. rectangular sequence;
2. DANTE sequence;
3. shaped sequence.

2.1 Rectangular Sequences

Rectangular sequences are single, soft pulses obtained like an ordinary hard pulse but with low-amplitude power of the radiofrequency field and a long pulse duration. Two main disadvantages are the low-frequency selectivity and the long excitation time.⁵

2.2 DANTE Sequence^{6,7}

The DANTE sequence is an ingenious system for selective excitation using high-power pulses. It consists of a sequence of 10–100 short, high-power pulses with a pulse angle $\phi < \pi/2$ and a repetition frequency $1/\tau$. The effect generated on a magnetic moment vector is similar to that of a soft rectangular pulse with a larger selectivity that improves as the number of pulses in the pulse train is increased. With respect to the soft rectangular pulse, the DANTE sequence generates a set of excitation bands at a frequency n/τ (where n is an integer 1, 2, 3, etc.) symmetrical with the transmitter frequency ω_0 .

Important improvements to the original DANTE sequence have increased the frequency selectivity (reducing the effect of side lobes of the excitation function) by pulse-shaping with DANTE⁸ and have enabled selective simultaneous excitation of two frequencies by double-DANTE sequences.⁹

2.3 Shaped Pulses

Selective relaxation experiments require the generation of sharp selective pulses that cannot be obtained from soft rectangular pulses. An almost ideal excitation profile requires smoothing of the side lobes in the frequency domain. This is now achieved by appropriate pulse-shaping procedures, which usually require a pulse-shaping spectrometer device.

Gaussian pulse shaping was one of the first shaping functions to be used.^{5,10,11} Now a number of different shaping functions are available to generate selective soft pulses for any multidimensional relaxation experiment. Tables 1 and 2 (from Kessler et al.)¹ show the main characteristics of the different soft excitation pulses and their ‘recommended’ applications.

3 THE DIPOLAR RELAXATION MECHANISM

In solution the exchange of magnetic energy between excited nuclei and the lattice occurs mainly through dipole–dipole interactions between $I = \frac{1}{2}$ nuclei. The efficiency of energy diffusion from ‘hot’ nuclei (excited) to the ‘cold’ lattice is a function of internuclear distances between spin- $\frac{1}{2}$ nuclei and the modulation of these internuclear vectors by dynamic processes, typical of molecules in solution. The time evolution of the z component magnetization of two spins I and S in a dipolar interaction has the form^{12,13}

$$\frac{d\langle I_z \rangle}{dt} = -\rho_I(\langle I_z \rangle - I_0) - \sigma_{IS}(\langle S_z \rangle - S_0) \quad (1)$$

$$\frac{d\langle S_z \rangle}{dt} = -\rho_S(\langle S_z \rangle - S_0) - \sigma_{SI}(\langle I_z \rangle - I_0) \quad (2)$$

where $\langle I_z \rangle$ and $\langle S_z \rangle$, and S_0 and I_0 are the z components and the equilibrium values of magnetization of spins I and S , ρ_I

^bE.g. ROESY.

^cDepends on the excitation sequence.

and ρ_S the direct self-relaxation rates, and $\sigma_{IS} = \sigma_{SI}$ the ‘cross-relaxation’ rates. In this case the relaxation process assumes an exponential decay with a rate constant R_1 , the spin–lattice relaxation rate:

$$R_1^i = \rho_i + \sigma_{ij} \quad (i = I, S), (j = S, I) \quad (3)$$

For multispin interaction, as occurs in complex systems of biomolecules, the ‘nonselective’ spin–lattice relaxation rate R_1^{NS} of an i nucleus interacting with neighboring j nuclei can be described by a modified version of Equation (3):

$$R_1^{\text{NS}} = \sum_{i \neq j} \rho_{ij} + \sum_i \sigma_{ij} + R^* \quad (4)$$

with the approximation of independent pairwise interactions and considering the contribution of nondipolar relaxation processes R^* .

The explicit form of ρ_{ij} and σ_{ij} in the case of intramolecular dipolar interactions are:

$$\rho_{ij} = \frac{1}{10} \frac{\gamma_H^4 \hbar^2}{r_{ij}^6} \left(\frac{3\tau_c}{1 + \omega_H^2 \tau_c^2} + \frac{6\tau_c}{1 + 4\omega_H^2 \tau_c^2} + \tau_c \right) \quad (5)$$

$$\sigma_{ij} = \frac{1}{10} \frac{\gamma_H^4 \hbar^2}{r_{ij}^6} \left(\frac{6\tau_c}{1 + 4\omega_H^2 \tau_c^2} - \tau_c \right) \quad (6)$$

where $\hbar$ is the reduced Planck's constant, γ_H and ω_H are the proton magnetogyric ratio and Larmor frequency respectively, r_{ij} the internuclear distance, and τ_c the effective correlation time which modulates the i - j magnetic interaction.

When the excited i nucleus relaxes with j nuclei at their thermal equilibrium, the 'cross-relaxation' term vanishes¹⁴⁻¹⁶ [as the difference between the second terms of equations (1) and (2) becomes zero] and equation (4) becomes:

$$R_{li}^{SE} = \sum_{i \neq j} \rho_{ij} \quad (7)$$

where R_{li}^{SE} is the selective spin-lattice relaxation rate.

Selective excitation of two (or more) resonances adds a selective cross-relaxation term to equation (7) and the relaxation process is driven by the biselective spin-lattice relaxation rate¹⁷ R_{li}^{BS} :

$$R_{li}^{BS} = \sum_{i \neq j} \rho_{ij} + \sigma_{ij} \quad (8)$$

Proton and ^{13}C nuclei can be regarded as limiting examples of complexity for dipolar relaxation analysis and, in both cases, the possibility of using spin-lattice relaxation rates for conformational investigations is based on the ability to dissect the complex relaxation process of a multispin system.

In principle, internuclear distances can be measured for biomolecules in solution provided that (1) they have a single predominant structure or a limited number of conformers and (2) a single ρ_{ij} or σ_{ij} can be experimentally measured. This can be achieved by selective spin-lattice relaxation techniques and by combining selective relaxation rates and nuclear Overhauser effects (NOEs) as described below.

As shown by equation (4) in nonselective spin-lattice relaxation experiments on proton nuclei, the measured relaxation rate is the sum of many terms related to all the direct and σ_{ij} cross-relaxation contributions. Thus, only limited information on molecular conformation and dynamics can be obtained from nonselective proton relaxation data since several different internuclear distances and correlation times determine the experiment rate. No structural information can be obtained from the conventional ^{13}C selective relaxation of protonated carbon atoms since the one-bond C-H interaction dominates the relaxation process, and conformational analysis by studying the relaxation of quaternary carbons is complicated by the multiplicity of long-range C-H interactions.^{18,19}

The selective excitation of single (or double) protons simplifies the nuclear relaxation pathway and can be performed by a variety of techniques.^{1,2,4,20} If the experimental conditions are such that the selective relaxation process of a nucleus involved in dipole-dipole interactions is described by the above equations, simple and reliable methods of calculation of relaxation parameters from selective relaxation measurements can be used, and structural and/or dynamic information can be obtained.

Although selective relaxation parameters can be efficiently used as tools to investigate conformational properties and biomolecular interactions in small and medium-size molecules, cross-relaxation processes may be profoundly altered under the slow motion conditions ($\omega_0 \tau_c \gg 1$) typical of large biomacromolecules such as proteins, nucleic acids, and polysaccharides. When these dynamic conditions apply, the rate of transfer of spin energy between nuclei becomes much larger than the rate of transfer of energy to the lattice. The process of propagation of the magnetization in the network of dipolar-coupled spins, known as 'spin diffusion',²¹ has the effect of destroying differences in spin-lattice relaxation rates in the molecules so that all tend to the same value.²²⁻²⁴

Analyzing the relaxation process on a short timescale, i.e. using the 'initial rate approximation', it has been possible to simplify the interpretation of the results on the basis of a hypothetical two-spin system, but large problems still remain due to the extensive overlapping resonances typical of biomacromolecular spectra.

Some novel one-dimensional (1D)²⁵⁻²⁷ and two-dimensional (2D)²⁸⁻³⁰ methods have recently eliminated the 'spin diffusion' process by exclusion of selected nuclei from the dipolar-coupled bulk proton network^{29,30} or by removing the interference of all protons other than the selected pair.²⁵⁻²⁷ In the era of 1D, 2D, three-dimensional, and multidimensional NMR these methods can open up a new age for the application of selective relaxation measurement to study large biomacromolecules.

4 GENERAL REMARKS ON SELECTIVE RELAXATION EXPERIMENTS

In order to perform selective relaxation experiments, the use of pulse sequences able to perturb the nuclear spin population is required. Initial relaxation rates can be obtained provided that the experiment is correctly carried out and that theoretical problems do not quench the dipolar relaxation strategy. As the recovery of the longitudinal component of nuclear magnetization very rarely follows a true exponential decay, it is important to analyze under what circumstances these undesired effects can be avoided. Unfortunately the main effects that alter the exponential behavior of the magnetization are intrinsic, as they arise in coupled spin systems and are due to dipole-dipole 'cross-relaxation' effects and scalar coupling.^{31,32}

4.1 Cross-Relaxation Effects

As shown by equations (1) and (2), the recovery of the longitudinal component of the magnetization is usually described by two constant rates ρ and σ , and only under special conditions is this behavior a pure exponential. This is the case

for ^{13}C magnetization measured under conditions of continuous broadband proton decoupling, where proton irradiation sets up and maintains a constant spin population of allowed energy levels such that cross relaxation no longer affects the recovery curve. Similar behavior is expected for selective proton relaxation in cases of weak dipolar coupling or when the effect of cross-relaxation diffusion is truncated using the initial slope approximation. In the latter case the experimental relaxation parameter is calculated by measuring the initial rates in the semi-logarithmic plot of reduced intensity $(I_0 - I_z)/2I_0$ vs. delay times. In more general cases, especially in biological systems, the presence of a network of dipolar-coupled spins induces cross-relaxation contributions that change the pure exponential decay. Nevertheless, at least for small and medium-size biomolecules and for dipolar interactions within a 3.5 distance, the initial rate approximation can be used to interpret the data in terms of two-spin systems and to calculate by numerical simulation the direct self-relaxation rate and the 'cross-relaxation' contributions. A more complex situation occurs when the fast motion conditions $\omega_0^2\tau_c^2 \ll 1$ do not hold, as in large biomolecules. Under these conditions, due to spin diffusion, the initial slope approximation is no longer valid, especially for long-range interactions, and only recently has it been possible to determine by virtue of synchronous nutation experiments^{25–27} the structural properties of proteins from cross-relaxation data obtained by selective relaxation measurements.

4.2 Scalar Coupling

In strongly coupled spin systems, the transition probabilities for the components of a spin multiplet are no longer equal. An important element of symmetry is thus lost, even though the excitation pulse acts equally on all multiplet components. Even for a single two-spin system AB, the zero quantum, single quantum and the double quantum transition probabilities do not assume the classical form,^{31–33} but a mixing term W_{AB} appears. It is this last term W_{AB} that causes different recovery curves for the components of a spin multiplet with a specific deviation from pure exponential magnetization decay.

However the perturbative effect of scalar coupling on the behavior of the magnetization recovery curve can be considered a priori. Moreover the 'classical' relaxation equations are still valid when $\Delta\omega/J > 10$, where $\Delta\omega$ is the difference in chemical shift between two spins and J is their scalar coupling constant. This is a general condition met in studying biological systems. Again the synchronous nutation experiment²⁷ has simplified the problem of correctly calculating the relaxation parameter in the presence of strong scalar coupling, by removing all scalar interactions between spins that are irradiated (active) and at Boltzmann equilibrium (passive). Although the effect of strong scalar coupling between irradiated (active) spins can still affect the recovery curve, its contribution can be taken into account by simple numerical analysis.

5 APPLICATION OF SELECTIVE RELAXATION TECHNIQUES IN BIOLOGICAL SYSTEMS

Many papers have fairly recently been published^{25,34–38} proposing the use of selective relaxation experiments to investigate biological systems. For simplicity, proton homonuclear

and heteronuclear interactions and their field of application will be treated separately.

5.1 Homonuclear Selective Relaxation Experiments

In ^1H homonuclear spin systems, the nonselective inversion recovery, $180^\circ\text{-}\tau\text{-}90^\circ$ pulse sequence gives partially relaxed spectra in which it is possible to follow the recovery of the Boltzmann equilibrium for each resonance by individual constant rates (R_1^{NS}) which are the sum of two contributions: the direct and the cross-relaxation terms [as described by equation (4)]. It has been shown by Freeman et al.¹⁴ that cross relaxation may be negligible provided that the 180° pulse selectively excites single-proton resonances. In particular, if the initial relaxation is monitored after selective population inversion of proton i , i.e., short delays are used between the selective and the nonselective observing 90° pulse, the initial recovery rate of the magnetization (R_{1i}^{SE}) is described by equation (7). At longer delay times, cross relaxation becomes significant, as can be observed from the intensity changes of the resonances of protons dipolarly coupled to the excited proton. It follows that selective excitation techniques can be used to achieve a simplification of the proton relaxation process and to calculate the selective dipolar relaxation contribution to the observed spin–lattice relaxation rate.

The initial selective relaxation rate R_{1i}^{SE} is an important parameter which can be used to obtain information on: (1) relaxation mechanisms, (2) molecular dynamics, and (3) molecular conformations.

1. In molecular systems which satisfy the extreme narrowing condition $(\omega_0\tau_c)^2 \ll 1$, for proton i , the ratio between the nonselective relaxation, R_1^{NS} , and R_{1i}^{SE} is diagnostic of the efficiency of the dipole–dipole relaxation mechanism, since this ratio, F_i , is equal to 1.5 for a relaxation pathway completely dominated by the $i\text{--}j$ proton dipolar interactions.³⁹
2. As shown in Figure 1, F_i also depends on $\omega_0\tau_c$ and, hence, for rigid isotropically reorienting molecules, motions can be quantified from the latter parameter.³⁹
3. The combined use of R_{1i}^{SE} and homonuclear Overhauser effects, NOEs, yields an absolute evaluation of σ_{ij} rates since, neglecting cross-polarization effects, the following relationship holds⁴⁰

$$\text{NOE} = \sigma_{ij}/R_i(\text{SE}) \quad (9)$$

where NOE is the Overhauser effect on proton i upon selective excitation of proton j .

The calculation of the cross-relaxation rate relative to a single $i\text{--}j$ dipolar interaction is also possible by the simultaneous double excitation of protons i and j . If selectivity in the double excitation can technically be achieved, the relaxation process is driven by the biselective relaxation rate, R_{1i}^{BS} , as shown by equation (8).

It should be noted that the initial conditions for the evaluation of R_{1i}^{BS} are critically important because the peak intensities observed in the partially relaxed spectra are determined by the relaxation process and the time-dependent $i\text{--}j$ NOE.^{31,41}

Homonuclear selective relaxation experiments are widely used to investigate different properties of biological systems. The most interesting approaches are related to the analysis of:

Figure 1 (a) Dependence of $F = R_i(\text{NS})/R_i(i)$ versus $\log \omega_0 \tau_c$. (b) Behavior of $RSE/1$ (1), $RNS/1$ (2), and σ_{ij} (3) for a two-spin system under different dynamic conditions; (1), (2), and (3) are readily generalized for proton i , involved in multiple interactions with several protons, $i \neq j$. 5.1.1 Conformational and Dynamic Properties of Biomolecules in Solution

The network of intramolecular dipolar connectivities in small to medium-size biomolecules can be easily evaluated by selective relaxation experiments. The most suitable approach consists first of calculating the cross-relaxation rates between selective proton pairs as the difference between selective and bisselective relaxation experiments:

$$\sigma_{ij} = R_{1i}^{\text{BS}} - R_{1i}^{\text{SE}} \quad (10)$$

$$\sigma_{ji} = R_{1j}^{\text{BS}} - R_{1j}^{\text{SE}} \quad (11)$$

in which $\sigma_{ij} = \sigma_{ji}$ are the cross-relaxation values obtained from analysis of the relaxation properties of the i and j

nuclei, respectively. Selective homonuclear NOE experiments can also be used to evaluate σ_{ij} . Figure 2 shows an example of proton-selective and bisselective experiments used for calculating σ_{ij} . The effect of the additional cross-relaxation contribution to the magnetization recovery process in the bisselective experiment, is evident.

As shown by equation (6) and Figure 3, σ_{ij} contains both structural (r_{ij}) and dynamic (τ_c) information.⁴² Constant calibration distances are required for the calculation of the effective correlation time τ_c . This is easily achieved by considering independent conformational distances as geminal interactions of CH_2 groups, *ortho* protons of aromatic residues, etc.

As shown in Figure 1, $F_1 = R_{1i}^{\text{NS}}/R_{1i}^{\text{SE}}$ can be used as a probe for molecular motion assuming as dominant the intramolecular dipolar mechanism. Carbon-13 relaxation measurements (see next section) obtained under broadband proton decoupling can also be used to map the distribution of motions along a biomolecule or to verify isotropic tumbling in systems with restricted internal flexibility. A detailed description of the modulation of the dipole-dipole interaction allows selected interproton distances, from which the solution conformation can be derived, to be calculated with confidence. From the first papers^{39,43,44} in which this approach was proposed, nearly every class of biological molecule was investigated: amino acids,^{43,45} peptides,⁴² carbohydrates,⁴⁶ oligosaccharides,^{47,48} drugs,^{49,50} natural products,^{37,51,52} etc.

Recently when the 2D approach for studying dipolar networks seemed to diminish the importance of these selective relaxation studies, a new selective experiment was proposed which enabled large macromolecules such as proteins to be investigated²⁵ (Figure 4). According to this new approach, one or two proton resonances are simultaneously excited by an amplitude modulated radiofrequency field which forces the magnetization vectors to undergo simultaneous motion defined as ‘synchronous nutation’.^{25–27} Time-dependent analysis under different initial conditions allows calculation of the direct self-relaxation rate or the ‘cross-relaxation’ term. In the ‘synchronous nutation’ experiment, the neighboring spins do not affect the magnetization behavior of the selectively isolated spin system even in the presence of the spin diffusion typical of slow molecular tumbling $\omega_0 \tau_c \gg 1$ conditions. Conformational studies (through selected-pair distance determination) by selective relaxation measurements in large biomacromolecules appear to be a valid alternative to the classical approach based on 2D analysis of dipolar-coupled spin systems.

5.1.2 Intermolecular Interaction: Ligand–Macromolecular Receptor

Ligand–macromolecule interactions can be detected by selective relaxation measurements. The formation of intermolecular adducts affects nonselective and selective spin–lattice relaxation rates to different extents, assuming that fast chemical exchange occurs between the bound and free environments with respect to both the chemical shift difference and the proton relaxation rate.⁵³

If only two environments are considered, the relaxation parameters are expressed by:

$$R_{\text{obs}}^A = \chi_f R_{1f}^A + \chi_b R_{1b}^A \quad (12)$$

Figure 2 Proton-selective and biselective partially relaxed spectra obtained by selective inversion of the magnetization of H-1' (a) and of both H-1'–H-3 (b) protons of a 0.15 mol dm⁻³ gentiobiose octaacetate solution in dimethyl sulfoxide-*d*₆. *T* = 300 K. The delay values between the selective and nonselective pulses were: 5, 10, 20, 40, 80, 100, 200, 400, 600, 800, 1000, 2000, and 10 000 ms

Figure 3 Isosigma contours for $\log \omega_0 \tau_c$ vs. interproton distances calculated from equation 6; the selected σ values are expressed in s⁻¹. (Reproduced by permission of Elsevier from N. Niccolai, L. Pogliani, C. Rossi, P. Corti, and W. A. Gibbons, *Biophys. Chem.*, 1984, **20**, 217)

where χ_f and χ_b are the ligand fractions in the free and bound environments. Since $\chi_f + \chi_b = 1$ and taking $\chi_b \ll 1$, equation (12) becomes:

$$R_{\text{obs}}^A = R_{\text{lf}}^A + \chi_b R_{\text{lb}}^A \quad (13)$$

Figure 4 Selective inversion–recovery measurements of the aromatic protons H^δ and H^ε of the tyrosine (Tyr) residue in bovine pancreatic trypsin inhibitor dissolved in ²H₂O at 327 K. The inset shows the aromatic region (between 8.2 and 5.8 ppm) of the 1D spectrum (eight scans); the arrows indicate the shifts of H^ε at 6.30 ppm and of H^δ at 7.20 ppm. Lower part: normal inversion–recovery measurement of H^ε in Tyr²³ using selective pulses and direct observation of H^ε. Upper part: inversion–recovery of H^δ using selective pulses and Hartmann–Hahn transfer from H^δ to H^ε. (Reproduced by permission of the American Chemical Society from B. Boulat, R. Konrat, I. Burghardt, and G. Bodenhausen, *J. Am. Chem. Soc.*, 1992, **114**, 5412)

where A = SE or NS. From equation (13) it emerges that only experimental parameters broadly affected by the ligand–macromolecular interaction make the second term of equation (13) significant. Binding of a ligand to a macromolecular receptor slows down its reorientation motion from $\omega_0 \tau_c \ll 1$ to $\omega_0 \tau_c \gg 1$. In diamagnetic systems where the dipole–dipole interaction is the dominant relaxation mechanism, entering into the slow-motion region does not significantly alter the nonselective spin–lattice relaxation rates [equation (4)]. On the contrary, the selective relaxation of the bound ligand can be expected to be quite different from that

Figure 5 $R_{1S}/1$ and $R_{1SE}/1$ of a proton pair versus $\omega_0\tau_c$ assuming a constant r_{i-j} distance (1.77 Å) for the $i-j$ dipolar interaction. The equilibrium between the ligand molecules in the bulk ($\omega_0\tau_c \ll 1$) and DNA-bonded ($\omega_0\tau_c \gg 1$) is also shown. (Reproduced by permission of Elsevier from C. Rossi, A. Donati, and M. R. Sansoni, *Chem. Phys. Lett.*, 1992, **189**, 278)

of the free ligand in solution as shown in Figure 5 for a ligand–DNA interaction.³⁶

Since the study of biomolecular interactions by selective relaxation measurement is based on a slowing of ligand molecular motion, the effect of the macromolecular receptor on the viscosity of the system must be considered. Temperature-dependent analysis of R_{1S}^{NS} can address this point. In fact as seen in Figure 5, fast-motion ($\omega_0\tau_c \ll 1$) and slow-motion ($\omega_0\tau_c \gg 1$) conditions show opposite slopes, so hypothetical, drastic changes in viscosity due to the receptor site can be monitored simply by following R_{1S}^{NS} dependence on temperature.^{36,54} This method is very powerful since it has a wide range of applications in biological systems. As the information is gained from selective relaxation rates of the ligand, ill-defined receptors in biological samples⁵⁵ such as blood whole cells etc. can be investigated and receptor purification followed.

A wide range of ligand–biomacromolecule interactions have been investigated by selective spin–lattice relaxation rate analysis;⁵⁶ these include enzyme–substrate,⁵³ drug–membrane interactions,⁵⁷ and recently ligand–DNA,³⁶ for the purpose of identifying potential mutagens and toxic compounds. This approach can also be used to calculate the association constant for the interaction processes.⁵⁸

5.1.3 Water Selective Relaxation in Large Organized Biological Systems

Water proton relaxation rates have been found to correlate with the physiological and pathological state of the cell as well as to the conformational state of cell constituents.^{59–61} Experimental evidence that water selective relaxation is faster than nonselective water relaxation rates in protein solutions and cell suspensions has focused attention on the relaxation mechanism of water protons in large organized

systems.^{38,62–65} The water spin–lattice relaxation (R_{1W}) may be described as the sum of two contributions:⁶⁶

$$R_{1W} = R_{1A} + R_{1B} \quad (14)$$

where R_{1A} and R_{1B} are the intra- and inter-molecular relaxation rates. The intramolecular term is due to:

$$R_{1B} = R_{1WW} + R_{1WM} \quad (15)$$

R_{1WW} is the dipolar contribution due to intramolecular water–water interactions and R_{1WM} that arising from water–macromolecule (or cell constituent) interactions.³¹ The latter interaction can yield direct ρ_{WM} and cross-relaxation σ_{WM} contributions from simultaneous water and macromolecule proton excitation:

$$R_{1WM} = \sum \rho_{WM} + \sum \sigma_{WM} \quad (16)$$

If the water relaxation rate is measured in the selective mode, only a small fraction of the macromolecule protons are excited and the σ_{WM} term disappears. It follows that in the presence of large biological surfaces:⁶⁵

$$R_{1W}^{NS} - R_{1W}^{SE} = \sum \sigma_{WM} \quad (17)$$

where R_{1A} and R_{1WW} are constants in nonselective and selective experiments respectively. Experimental evidence obtained for protein solutions and cell culture suspensions shows that the difference between nonselective and selective relaxation rates [equation (17)] are not only due to the dynamic change in the solvent molecules but also to dipolar intermolecular connectivities between the solvent and the surface of hydrophilic regions of macromolecules. This suggests that it would be useful to use the complete set of relaxation parameters, such as R_{1W}^{NS} , R_{1W}^{SE} , and σ_{WM} to investigate the physiological and pathological state of cells or to study drug–cell and virus–cell interactions;⁶⁷ R_{1W}^{NS} to probe essentially dynamic features of the heterogeneous systems, and R_{1W}^{SE} and σ_{WM} to study the water–macromolecule magnetic energy transfer process, which is intimately linked to the solvent exposed interface structure assumed by the biological material.

5.2 Heteronuclear Selective Relaxation Experiments

Our discussion will be limited to the ^{13}C nucleus, due to its importance for verifying dynamic and structural information on biological systems.

In spite of the low sensitivity of heteronuclei with respect to protons, several advantages exist. Carbon-13 signals are spread over a large chemical shift range (over 300 ppm). The carbon resonances can be treated as single resonances removing proton scalar coupling by a broadband decoupling pulse. Under these conditions the carbon relaxations can be regarded as pure exponential, determined by a single contribution: the direct self-relaxation term. Furthermore, relaxation contributions due to intermolecular interactions are seldom significant (as the carbons are shielded by the proton surface) and, in natural abundance experiments, homonuclear ^{13}C – ^{13}C dipolar interactions are rare due to ^{13}C isotopic dilution. These properties make carbon relaxation a suitable parameter for investigating solution properties of biomolecules.

5.2.1 ^{13}C Selective Relaxation

In conventional ^{13}C relaxation experiments (obtained by broadband proton decoupling), cross relaxation between carbon nuclei is ignored and the measurement gives the selective, direct carbon spin–lattice relaxation rate:

$$R_{1C}^{\text{SE}} = \sum \frac{1}{10} \frac{\hbar^2 \gamma_H^2 \gamma_C^2}{r_i^6} \left[\frac{3\tau_c}{1 + \omega_C^2 \tau_c^2} + \frac{6\tau_c}{1 + (\omega_H + \omega_C)^2 \tau_c^2} + \frac{\tau_c}{1 + (\omega_H - \omega_C)^2 \tau_c^2} \right] \quad (18)$$

R_{1C}^{SE} of protonated carbons are dominated by the dipolar interaction between bonded proton–carbon nuclei.^{17,18} In this case the internuclear proton–carbon distance can be assumed to be constant and the effective correlation time calculated. In flexible molecules, a mapping of dynamic properties may be obtained from the R_{1C}^{SE} of different carbons. If continuous broadband proton decoupling is replaced by a selective 180° proton pulse, applied to the i nucleus, with the first 180° carbon pulse the initial rate of the longitudinal magnetization of carbon is:^{68–70}

$$R_{1C}^{\text{BS}} = R_{1C}^{\text{SE}} + \xi \sigma_{\text{CH}_i} \quad (19)$$

where R_{1C}^{BS} is the biselective carbon relaxation rate $\xi = \gamma_H/\gamma_C$ and σ_{CH} the single proton–carbon ‘cross-relaxation’ term. When the selective 180° proton pulse is replaced by a proton perturbation which can invert the spin equilibrium of the entire proton population, the carbon relaxation is described by:^{69–71}

$$R_{1C}^{\text{NS}} = R_{1C}^{\text{SE}} + \xi \sum \sigma_{\text{CH}_i} \quad (20)$$

The following dynamic and structural information is obtained by comparing R_{1C}^{SE} , R_{1C}^{BS} , and R_{1C}^{NS} measurements.

5.2.1.1 Dynamic analysis. The $R_{1C}^{\text{NS}}/R_{1C}^{\text{SE}}$ ratio takes a value in the range 2.99–1, depending on the molecular motion. In this way the value of the $R_{1C}^{\text{NS}}/R_{1C}^{\text{SE}}$ ratio allows the correlation times for each molecular moiety to be determined (or at least the limit value of τ_c). The $R_{1C}^{\text{NS}}/R_{1C}^{\text{SE}}$ ratio in particular is a very useful parameter for evaluating the effective correlation time of nonprotonated carbon atoms.

5.2.1.2 Structural analysis. The difference between R_{1C}^{BS} and R_{1C}^{SE} gives the cross relaxation term $\sigma_{\text{C}_i\text{H}_A}$ for each ^1H – ^{13}C magnetic interaction which contains distance information. This method has been demonstrated with different natural products, giving reliable results.^{69–71}

5.2.2 Selective Proton–Carbon NOEs

Several authors have shown that selective proton–carbon NOEs, (^1H) ^{13}C -NOE, can be generated.^{72–74} When a selective pulse is used to saturate a single proton then ‘cross relaxation’ between the irradiated proton and the carbon microenvironment occurs. The (^1H) ^{13}C -NOE is described by:^{75,76}

$$(^1\text{H}_A)^{13}\text{C}_i - \text{NOE} = \frac{\sigma_{\text{C}_i\text{H}_A}}{R_{1C}^{\text{SE}} + R_{1C}^*} \quad (21)$$

Figure 6 Carbon-13 spectra of 0.5 mol dm^{−3} rifamycin in CDCl₃ recorded on a Varian XL-200 spectrometer at 296 K: (a) ^{13}C spectrum after irradiation of the phenolic hydroxyl proton; (b) as (a) but with the decoupler set ‘off-resonance’. (c) Difference spectrum (b)–(a). The presaturation selective pulse on the phenolic hydroxyl proton had a 10 s duration and 0.5 W power. During the acquisition of the FIDs the decoupler was on with a power of 4 W in the broadband mode. The structure of rifamycin S is shown. (Reproduced by permission of the American Chemical Society from N. Niccolai et al.⁷⁵)

where $\sigma_{\text{C}_i\text{H}_A}$ is the selective ‘cross relaxation’, R_{1C}^{SE} the selective carbon relaxation rate, and R_{1C}^* the relaxation contribution due to nondipolar interactions [in paramagnetic systems this term often quenches the (^1H) ^{13}C -NOE]. Thus by combining selective NOEs with carbon relaxation rates, specific distance calculations can be obtained.

Although care must be taken in dealing with large macromolecules when magnetization diffusion occurs between spins, this method has been usefully applied to investigate the conformation of biological molecules such as antibiotics, peptides, natural components,^{77–79} etc. Figure 6 illustrates the capacity of (^1H) ^{13}C - NOE to discriminate the carbon microenvironment by selective proton perturbation.⁷⁵

1 INTRODUCTION

Many of the biologically relevant dynamic processes that take place in naturally occurring materials may be considered to be slow on the NMR timescale. This implies that the characteristic frequencies of the motions are comparable to or lower than the width of the NMR spectra that would be obtained in the absence of any molecular motion. Since virtually all nuclei commonly employed for NMR studies of biological systems yield rigid lattice spectra less than 1 MHz wide, a slow process may be defined for present purposes as one whose correlation times τ_C are longer than $(2\pi \times 10^6)^{-1}$ s. This article describes how NMR can be used to investigate such motions, with particular reference to biological studies.

There exists a wide range of NMR techniques available for probing low-frequency molecular dynamics. The methods themselves are by no means applicable only to biological systems, and indeed many of them were originally developed primarily to study synthetic materials. Most of the techniques are discussed in detail in other entries of this Encyclopedia. As far as NMR-observable nuclei are concerned, ^1H , ^{13}C , ^{14}N , and ^{31}P , which are, of course, abundant in biologically relevant compounds, can all be used in principle to investigate slow motions. In addition, the use of ^2H -labeled materials has now become almost commonplace, and has permitted highly detailed site-specific dynamic NMR studies even in extremely complex systems.

Spin–lattice relaxation rates $1/T_1$ are essentially measures of the amplitudes of motional processes occurring at the Larmor frequency ω_0 of the probe nucleus. Thus, measurement of T_1 as a function of ω_0 provides a means of determining the motional frequency spectrum. For purposes of resolution and sensitivity, commercial spectrometers employ high magnetic fields. In the case of protons, for example, $\omega_0/2\pi$ ranges between 60 and 750 MHz, so that measurement of ^1H T_1 on a complete range of standard spectrometers could yield dynamic information over about one order of magnitude on the frequency scale. Field cycling techniques^{1,2} enable the determination of T_1 at frequencies lower than the standard high Larmor frequencies and greatly extend the range of

the motional frequency spectrum that can be observed. This has particular significance for the study of slow motions in complex systems, where several processes may contribute to the overall spin relaxation mechanism. The application of field cycling for measuring ^1H T_1 dispersions has been instrumental in characterizing collective motions in proteins³ and in phospholipid membranes.⁴

Whereas spin–lattice relaxation is essentially nonadiabatic and reflects exclusively those motions with frequency components at ω_0 , transverse spin relaxation is affected in addition by adiabatic dephasing mechanisms due to processes with smaller rate constants, on the order of the rigid lattice linewidth. Transverse relaxation times are most commonly measured using spin echo experiments in which inhomogeneous (i.e., static) contributions to the magnetization dephasing process are refocused. The simplest spin echo experiment consists of a 90° pulse followed by a delay τ , after which a refocusing pulse (180° or 90°) is applied. An echo is formed a period τ after the second pulse, the intensity of which decreases with increasing τ .^{5,6} If the dominant motional process is fast in the sense that the correlation time τ_C is shorter than τ then the echoes decay exponentially, and it is possible to extract a single transverse relaxation time T_{2E} . For slower motions, however, for which τ_C is comparable to or longer than τ , the effective relaxation rate itself depends on the value of τ ,⁷ and the echo decay can no longer be described by a single exponential. In fact, the precise form of the echo decay function depends sensitively on the nature of the underlying motional process.

Although this phenomenon has been understood since the early days of pulsed NMR spectroscopy,⁷ its potential applications in the study of slow processes in complex phases such as biological membranes have been recognized only relatively recently.⁸ In practice, rather than measure the form of the simple spin echo decay function, multipulse trains such as the Carr–Purcell–Meiboom–Gill (CPMG) sequence^{9,10} and its quadrupolar analog¹¹ are employed. In these experiments, instead of a single refocusing pulse, a series of equally spaced refocusing pulses is applied, resulting in the formation of an echo train. For samples containing a single spin label, the echoes decay monoexponentially with a time constant T_{2E}^{CP} , which depends on the pulse spacing τ . The form of the pulse spacing variation of T_{2E}^{CP} is indicative of the distribution of correlation times for the responsible motional processes, whilst the absolute values of T_{2E}^{CP} reflect their effective amplitudes.¹²

Transverse spin relaxation techniques, employing either ^2H or ^{31}P as the probe nuclei, have been applied to study a variety of mechanisms such as collective motions^{12–15} and lateral diffusion⁸ in biological membranes. An alternative but related approach for observing slow motions involves rotating frame relaxation measurements.¹⁶ The locking-field dependence of $T_{1\rho}$ is analogous to the pulse spacing dependence of T_{2E}^{CP} ,¹⁷ and has been exploited to characterize low-frequency dynamics in phospholipid membranes.^{18,19}

Ultraslow exchange NMR methods directly measure the time variation of the resonance frequency as a result of molecular reorientation.²⁰ The basic requirement for all experiments of this type can be expressed by the relation $T_1 > \tau_C > T_{2E}$. This approach affords the possibility to study processes with effective correlation times of up to several seconds, depending on T_1 of the resonant nucleus. In the two-dimensional version of the experiment,²¹ cross peaks

appear connecting the different frequencies experienced by the spins. In general, the resonance frequency of a particular spin is determined by the orientation Ω of the dominant spin interaction tensor relative to the static magnetic field. Consequently, it is rather straightforward to interpret the exchange spectra in terms of the time variation of Ω .

The choice of experiment to use for investigating a particular system will be dictated by the expected timescale of the motional process of interest and, of course, by the materials available. In the case of ultraslow motions, one of the exchange type of experiments would be most suitable, although the condition $\tau_C > T_{2E}$ is rarely fulfilled in biological systems. For complex collective and/or low-amplitude processes, one of the spin relaxation techniques (T_1 , T_{2E}^{CP} , or $T_{1\rho}$) would be most appropriate. The field cycling 1H T_1 approach undoubtedly offers the greatest dynamic range—typically six orders of magnitude in frequency. This is especially useful when dealing with collective motions with broad distributions of correlation times. The method is limited at low frequencies, however, by internal field effects, which render ambiguous the interpretation of any cutoffs that may appear in the T_1 dispersion profiles. The same restrictions apply to $T_{1\rho}$ measurements but not to T_{2E}^{CP} studies. This, together with the simplicity of the experimental techniques, makes pulse-frequency-dependent T_{2E}^{CP} experiments particularly attractive for characterizing slow motions in biological systems. In the following sections, frequency-dependent transverse relaxation is described in more detail, with particular reference to its application in the study of slow motions in biological membranes.

2 OBSERVATION OF SLOW MOTIONS: PULSE-FREQUENCY-DEPENDENT SPIN RELAXATION

Nuclear spin relaxation times provide information regarding the timescale, symmetry and amplitude of molecular motion. In order to distinguish between different possible mechanisms, it is advisable if not essential to exploit each of these three aspects of the dynamics. A simple and effective method for achieving this in the slow motional regime involves determining the pulse spacing and orientation dependence of transverse spin relaxation times T_{2E}^{CP} .

2.1 Spin Echo Pulse Trains

The CPMG pulse sequence^{9,10} and its quadrupolar equivalent¹¹ measures the decay of successive spin echoes as illustrated schematically in Figure 1 (top). If the motional correlation time τ_C is of the same order of magnitude as the pulse spacing τ then the echo decay rate $R_{2E}^{CP} = 1/T_{2E}^{CP}$ depends on τ . Generally, the form of the pulse spacing dependence is characteristic of the motion responsible for the relaxation. This is illustrated in Figure 1 (bottom), which shows R_{2E}^{CP} pulse frequency dispersions [$R_{2E}^{CP}(\omega)$, $\omega = 1/\tau$] for three different types of motion. The Markov process with a single correlation time τ_C exhibits a Lorentzian dispersion with a plateau at low frequencies ($\omega \ll 1/\tau_C$) and an inverse square dependence $R_{2E}^{CP} \propto \omega^{-2}$ at higher frequencies.²² More

Figure 1 Top: Schematic of CPMG pulse sequence, showing echo decay. Bottom: Dependence of transverse relaxation rate R_{2E}^{CP} on pulse frequency $\omega = 1/\tau$ for (a) a single Markov process, and (b) three-dimensional and (c) two-dimensional collective orientational fluctuations

complex processes exhibit, in addition, an intermediate dispersion regime characteristic of the motion. Thus, collective orientational fluctuations provide a $R_{2E}^{CP} \propto \omega^{-1/2}$ dispersion in ‘three-dimensional’ phases (e.g., nematic liquid crystals),²³ whilst in ‘two-dimensional’ phases (e.g., bilayer membranes), the relaxation rate is inversely proportional to the pulse frequency: $R_{2E}^{CP} \propto \omega^{-1}$.^{12,15} The experimentally accessible frequency range of R_{2E}^{CP} depends, in general, on the sensitivity of the observed spin and on the form of the relaxation dispersion. For ^{31}P , in biological membranes, for example, it is possible to measure R_{2E}^{CP} at frequencies between 10^2 and 10^5 s⁻¹, which is sufficient to cover the relevant slow motional regime.¹⁵

There are two possible approaches to the analysis of transverse spin relaxation measurements, and some consideration should be given as to which method is most appropriate for each individual case. Motional narrowing limit expressions, which are usually adequate for the interpretation of spin–lattice relaxation experiments, cannot always be applied to transverse relaxation. In particular, for systems undergoing slow motions, it will generally be necessary to solve numerically the equations of motion for the relaxing spins.

2.2 Full Numerical Analysis

The starting point for a full numerical analysis of spin relaxation is the stochastic Liouville equation^{24,25}

$$\frac{\partial}{\partial t} \hat{\rho}(\Omega, t) = -\frac{i}{\hbar} \hat{\mathcal{H}}^x(\Omega) \hat{\rho}(\Omega, t) - \hat{\Gamma}(\Omega) [\hat{\rho}(\Omega, t) - \hat{\rho}_{eq}(\Omega)] \quad (1)$$

which describes the time dependence of the spin density matrix $\hat{\rho}(\Omega, t)$ under the influence of the spin Hamiltonian $\hat{\mathcal{H}}^x(\Omega)$ and the stochastic operator $\hat{\Gamma}(\Omega)$, for the various motional processes. The Euler angles Ω define the orientation of the dominant spin interaction tensor relative to a set of laboratory axes. Fortunately, for the purposes of interpreting transverse relaxation rates due to slow motions, it is often possible to separate the coupled differential equations [see equation (1)] into independent subsets describing the time variation of specific density matrix elements. Thus, the relevant part of equation (1) can be represented by a reduced set of differential equations, written in matrix form as^{26–28}

$$\frac{\partial}{\partial t}[\rho_{ij}(\Omega, t)] = -[i\mathbf{W}(\Omega) + \mathbf{K}(\Omega)][\rho_{ij}(\Omega, t)] \quad (2)$$

where $\rho_{ij}(\Omega, t)$ are the single quantum coherence components of $\hat{\rho}(\Omega, t)$, with $j = i \pm 1$. $\mathbf{K}(\Omega)$ is a rate matrix with elements determined by the discretized stochastic operator $\hat{\Gamma}(\Omega)$.^{26,27} Thus, $K(\Omega_{mn})$ is the rate constant for population transfer from site n to site m and $K(\Omega_{mm}) = -\sum_{n \neq m} K(\Omega_{nm})$. The diagonal matrix $\mathbf{W}(\Omega)$ contains the free precession frequencies for each site, m . In order to solve equation (2) it is convenient first to symmetrize $i\mathbf{W}(\Omega) + \mathbf{K}(\Omega)$ by a similarity transformation and then apply an efficient eigenvalue method.^{29,30}

Spin echo experiments can be simulated by successive application of equation (2) to describe each stage of the pulse sequence.^{31,32} Refocusing pulses can be treated as ideal rotations, inducing an instantaneous 180° phase shift in $\rho_{ij}(\Omega, t)$. The transverse relaxation rate R_{2E}^{CP} for a given pulse spacing τ is then³³

$$R_{2E}^{CP} = -\ln[M(2\tau)/M(0)]/2\tau \quad (3a)$$

$$M(t) = \sum_m \sum_i \rho_{i i-1}(\Omega_m, t) \quad (3b)$$

Note that for a homogeneous system, it is not necessary to evaluate the entire CPMG sequence, but it suffices to calculate just the first echo and apply equations (3a) and (3b).³⁴

2.3 Motional Narrowing Limit Expressions

For slow low-amplitude processes, it is conceivable that motional narrowing limit theory³⁵ may be applied to account for transverse spin relaxation. Exact analytical expressions for R_{2E}^{CP} valid in this regime have been derived.^{7,17,22} A useful approximate version of these derivations is^{23,33}

$$R_{2E}^{CP} \approx \frac{3}{2} C J_0^{\text{lab}}(\omega) \quad (4)$$

where $J_0^{\text{lab}}(\omega)$ is the spectral density of the motion at the pulse frequency $\omega = 1/\tau$ and C is the effective interaction strength parameter (e.g., $C = \frac{2}{3} \langle \Delta \sigma^2 \rangle$ for ^{31}P and $C = \frac{3}{8} \langle (e^2 q Q / \hbar)^2 \rangle$ for ^2H). For certain dynamic models, analytical expressions are available or can be derived for $J_0^{\text{lab}}(\omega)$. Otherwise, they may be evaluated numerically using the same finite grid point approach^{26,27} described above. In this case, we have^{36,37}

$$J_M^{\text{lab}}(\omega) = (F_{20}^{\text{mag}})^{-2} \left[\sum_{m,n} F_{2M}^{\text{lab}}(\Omega_m) F_{2M}^{\text{lab}*}(\Omega_n) X_m^{(0)} X_n^{(0)} \times \sum_k X_m^{(k)} X_n^{(k)} j^{(k)}(\omega) \right] \quad (5a)$$

$$j^{(k)}(\omega) = \frac{8}{\pi^2} \frac{\lambda^{(k)}}{(\lambda^{(k)})^2 + (\frac{1}{2}\pi\omega)^2} \quad (5b)$$

where $\lambda^{(k)}$ and $X^{(k)}$ are the eigenvalues and corresponding eigenvectors of the stochastic operator $\mathbf{\Gamma}$, obtained by diagonalizing the symmetrized rate matrix $\mathbf{K}^s$. The $F_{2M}^{\text{lab}}(\Omega_m)$ are the components of the magnetic interaction tensor for the m th site, expressed in the laboratory axis system (z parallel to $\mathbf{B}_0$). Similarly, F_{20}^{mag} is the zeroth component of the interaction tensor expressed in its principal axis system. Note that the Lorentzian reduced spectral density $j^{(k)}(\omega)$ defined above uses the inverse pulse spacing as the frequency variable, and for this reason differs from standard expressions for spectral densities in magnetic resonance, which generally involve the Larmor frequency ω_0 .

Combining equations (4), (5a), and (5b), we obtain a general expression for the transverse relaxation rate:

$$R_{2E}^{CP} = \frac{3}{2} C \sum_l P(l) J_0^{(l)\text{lab}}(\omega) \quad (6)$$

where the summation index l specifies the effective motional modes and $P(l)$ is the respective mode amplitude. In the case of collective motions, the spectrum of modes is expected to be continuous, and the summation in equation (6) can be replaced by an integral.

Transverse spin relaxation rates are invariably measured in the laboratory frame, and therefore depend on the spectral densities $J_M^{\text{lab}}(\omega)$ [see equation (4)]. On the other hand, dynamic models are generally defined with respect to local symmetry axes and the respective spectral density functions $J_M^{\text{loc}}(\omega)$ evaluated relative to these axes. The transformation between laboratory and local axis systems leads to a simple expression for the anisotropy of R_{2E}^{CP} .³⁸

$$R_{2E}^{CP} = \frac{3}{2} C \left[\frac{1}{4} (3 \cos^2 \theta_N - 1)^2 J_0^{\text{loc}}(\omega) + 3 \sin^2 \theta_N \cos^2 \theta_N J_1^{\text{loc}}(\omega) + \frac{3}{4} \sin^4 \theta_N J_2^{\text{loc}}(\omega) \right] \quad (7)$$

where θ_N refers to the angle between the static magnetic field and the local axis system. In a powder sample, all values of θ_N are observed, and the relaxation is in general multiexponential. For macroscopically aligned samples, it is possible to measure R_{2E}^{CP} as a function of θ_N and hence determine each of the three $J_M^{\text{loc}}(\omega)$. With this information, it is possible to determine the overall symmetry of the motion, without recourse to any specific model.

Interestingly, equations (5) and (7), describing the dispersion and anisotropy of R_{2E}^{CP} , are qualitatively valid over a dynamic range that extends beyond the limits usually associated with motional narrowing theory.³⁹ However, it should be stressed that these simple expressions are not always suitable, and, when in doubt, it is advisable to use the full numerical approach discussed above.

3 CHARACTERIZATION OF SLOW MOTIONS: TRANSVERSE SPIN RELAXATION IN BIOLOGICAL MEMBRANES

The majority of NMR studies of biological membranes have employed model systems whose composition is well defined and therefore permits more detailed investigations of specific aspects of membrane behavior. In this section, we present an instructive example of the application of NMR transverse spin relaxation methods to study low-frequency molecular dynamics in a biological model membrane. The particular system studied is a dispersion of dimyristoylphosphatidylcholine (DMPC) in water. From a biological point of view, it is the liquid crystalline (L_α) phase of this system that has received most attention. In this phase, the phospholipid molecules arrange in bilayers, separated by water, with the hydrophobic carbon chains oriented towards the center of the bilayer as illustrated in Figure 2. The most commonly employed preparation methods yield dispersions of approximately spherical multilamellar vesicles (see Figure 2). The mean value and variance of the vesicle radius distribution, however, depend significantly on the method of preparation employed.⁴⁰ Alternatively, macroscopically oriented samples can be obtained by incorporating thin layers of the DMPC/water mixture between thin glass plates (see Figure 2).⁴¹

3.1 Multilamellar Vesicles

It was pointed out in the previous section that transverse spin relaxation rates R_{2E}^{CP} depend on the sample orientation, the pulse frequency, and the spin interaction strength. Independent measurement of these three effects, however, is complicated to some extent by the use of vesicle samples. Since multilamellar vesicles are, in effect, isotropic powders, all orientations θ_N are represented, and therefore relaxation is generally multiexponential [see equation (7)]. In principle, it is possible to determine both the anisotropy and the pulse frequency dependence by Fourier transforming the final echoes of CPMG trains for different numbers of echoes, n , at each pulse frequency. This procedure, however, is time and labor-intensive, and alternative methods have usually been employed to extract the desired information. For homogenous samples with a single effective spin label, it is possible to exploit equation (7), so that the measured amplitude $M(2n\tau)$ of the n th echo in a CPMG experiment is

$$M(2n\tau) = M_0 \int_0^1 \exp\left\{-\left[\frac{1}{4}(3\cos^2\theta_N - 1)^2 F_0 + 3\sin^2\theta_N \cos^2\theta_N F_1 + \frac{3}{4}\sin^4\theta_N F_2\right]2n\tau\right\} d\cos\theta_N \quad (8)$$

and the decay curve for a given pulse spacing τ may be fitted by independently varying the three parameters F_0 , F_1 , and F_2 . Although equation (8) is strictly correct only in the motional narrowing limit, where the parameters F_M can be identified with the spectral densities $J_M^{loc}(\omega)$, it may be usefully applied in any regime provided that for each individual orientation θ_N the spins relax monoexponentially.

Figure 3, shows ^{31}P and ^2H scaled transverse relaxation rates, $R_{2E}^{CP}/\Delta\nu^2$ as functions of pulse frequency ω for 2-[14,14,14- d_3]DMPC (see Figure 2) multilamellar vesicles. The ^{31}P relaxation rates were measured using the standard CPMG

pulse sequence with spin lock proton decoupling.⁴² For ^2H , the quadrupolar CPMG sequence¹¹ was employed without proton decoupling. Results are shown for pure DMPC bilayers (open circles), DMPC/4 mol% gramicidin (filled diamonds), and DMPC/40 mol% cholesterol (open triangles), and in each case refer to the $\theta_N = 45^\circ$ orientation, extracted from CPMG echo decays using equation (8). Two important conclusions may be drawn from the results in Figure 3, independently of possible dynamic models. First, the evident frequency dependence of the rates indicates that slow motional processes are responsible for transverse relaxation. Moreover, the fact that the measured dispersion is in all cases approximately given by $R_{2E}^{CP} \propto \omega^{-1}$ suggests a superposition of different modes with frequency components in the 10^2 – 10^5 s $^{-1}$ regime probed specifically in the experiments. The second notable aspect of the results in Figure 3 is that the scaled rates $R_{2E}^{CP}/\Delta\nu^2$ are, to within experimental error, the same for ^{31}P and ^2H . The spectral parameter $\Delta\nu$ is defined as the measured frequency difference between the 0° and 90° singularities in the powder spectra. Thus, $\Delta\nu^2 \propto C$, and we find that the spin-interaction-independent (i.e., purely dynamic) contributions to the relaxation rates for ^{31}P and ^2H are identical. In other words, the lipid headgroup (^{31}P) and the *sn*-2 chain methyl group (^2H) undergo the same low-frequency motions, despite the fact that they are located at opposite extremities of the lipid molecule (see Figure 2). This indicates that the effective dynamic processes are of a mesoscopic nature. In comparing the ^{31}P and ^2H results, it is also worth pointing out that ^{31}P provides markedly superior signal-to-noise ratio and a correspondingly wider dynamic range than ^2H , and there is a good case for proposing ^{31}P as the nucleus of choice for low-frequency dynamics studies of biological membranes.

The results in Figure 3 evaluated for the $\theta_N = 45^\circ$ orientation reflect the most rapidly relaxing component of the multiexponential decay. However, a second slowly relaxing component corresponding to the 90° orientation can also be detected in the ^{31}P CPMG experiments. The scaled ^{31}P relaxation rates are shown in Figure 4. Interestingly, at low frequencies, a plateau appears in the $R_{2E}^{CP}/\Delta\nu^2$ dispersion plot. What is more, the ratios between the plateau values for the different samples are different from the corresponding ratios found for the rapidly relaxing component.

Figure 5 shows the ^{31}P scaled transverse relaxation rates measured for pure DMPC vesicles at four different magnetic fields between 4.7 and 11.7 T. Note that in the case of ^{31}P , it is modulation of the chemical shift anisotropy that is responsible for transverse relaxation. Since the effective chemical shift anisotropy is determined by B_0 ($\Delta\nu \propto B_0$), it follows that the spin interaction strength parameter C also depends on the magnetic field ($C \propto B_0^2$). Thus, if the dynamic behavior of the membrane is unaffected by the presence of magnetic fields, the scaled relaxation rates $R_{2E}^{CP}/\Delta\nu^2$ should be independent of B_0 . The results in Figure 5 show that the higher frequency processes ($\geq 10^3$ s $^{-1}$), monitored by the rapidly relaxing component [Figure 5(a)], are virtually unaffected by the presence of the magnetic field, whereas the low-frequency motions ($\leq 10^3$ s $^{-1}$), reflected by the slowly relaxing component [Figure 5(b)], are apparently suppressed at higher magnetic fields.

NMR studies of slow motions in multilamellar vesicles have focused principally on two types of process, namely lateral diffusion across a curved surface⁸ and collective

Figure 2 Dimyristoylphosphatidylcholine (DMPC) molecule with ^2H and ^{31}P nuclei sites indicated. Also shown are schematic representations of multilamellar vesicles, oriented bilayers, and the collective splay mode for director fluctuations in biological membranes

Figure 3 (a) Scaled ^{31}P transverse relaxation rates $R_{2E}^{CP}/\Delta\nu^2$ measured as functions of pulse frequency ω for hydrated DMPC (open circles), DMPC/4 mol% gramicidin (filled diamonds), and DMPC/40 mol% cholesterol (open triangles) multilamellar vesicles at 313 K. Results refer to the rapidly relaxing 45° orientation. (b) Scaled ^2H transverse relaxation rates $R_{2E}^{CP}/\Delta\nu^2$ measured for the same samples under the same conditions. Solid lines are included as guides to the eye

orientation fluctuations.^{13,15,43} Both of these mechanisms can be considered mesoscopic in that they involve long-range orientational correlations. In the case of collective motions, a low-frequency cutoff in the relaxation dispersion is expected if long-wavelength fluctuation modes are suppressed. This could arise as a result of the finite size of the particles themselves. Alternatively, magnetic damping of the low-energy modes might occur owing to coupling between the NMR static magnetic field and the anisotropic diamagnetic susceptibility of the vesicles.⁴⁴ Simple models for lateral diffusion over a

Figure 4 Scaled ^{31}P transverse relaxation rates $R_{2E}^{CP}/\Delta\nu^2$ measured as functions of pulse frequency ω for hydrated DMPC (open circles), DMPC/4 mol% gramicidin (filled diamonds) and DMPC/40 mol% cholesterol (open triangles) multilamellar vesicles at 313 K. Results refer to the slowly relaxing 90° orientation. Solid lines are included as guides to the eye

curved surface do not predict such a magnetic-field-dependent low-frequency cutoff. Apparently, the measured $R_{2E}^{CP}/\Delta\nu^2$ dispersion profiles indicate that collective motions play a major role in the relaxation mechanism of multilamellar vesicles. However, the quantitative analysis of these measurements is inevitably limited by the sample heterogeneity. Indeed, it is most likely that the dominant relaxation mechanism depends on the vesicle size and that in any particular sample there may be two or more distinct processes that contribute to the overall measured echo decays.

3.2 Oriented Membrane Samples

The problems associated with the use of multilamellar vesicles for studying membrane dynamics have long been recognized, and alternative methods of sample preparation have been proposed. For example, spherical supported vesicles, prepared by condensing membrane bilayers onto spherical silica beads, have been used to measure lateral diffusion rates of lipid molecules.⁴⁵ The silica beads employed have extremely narrow distributions of radii, and therefore provide virtually monodisperse vesicles. An alternative approach that seeks to avoid the effects of lateral diffusion involves the use of oriented samples.⁴¹ In this case, the membrane bilayers are uniaxially aligned on glass plates such that the bilayer normal and the plate normal are coincident. Lateral diffusion of the molecules no longer induces any angular reorientation of the lipid molecules, and therefore is ineffective as a spin relaxation mechanism for isolated spins such as ^2H or decoupled ^{31}P . Results obtained for oriented DMPC bilayers show R_{2E}^{CP} anisotropies and pulse frequency dispersions consistent with those obtained for multilamellar vesicles, and support the

Figure 5 Scaled ^{31}P transverse relaxation rates $R_{CP}/2E/\Delta v^2$ measured as functions of pulse frequency ω for hydrated DMPC at magnetic fields of 4.7 T (filled circles), 7.0 T (open circles), 9.3 T (filled squares), and 11.7 T (open squares): (a) for the rapidly relaxing 45° orientation; (b) for the slowly relaxing 90° orientation. Solid lines are included as guides to the eye

conclusion that collective motions play a major role in the transverse spin relaxation.^{12,46}

4 EVALUATION OF VISCOELASTIC PROPERTIES: COLLECTIVE ORIENTATIONAL FLUCTUATIONS

Having identified collective motions as a dominant transverse relaxation process, it then remains to apply a suitable

model in order to evaluate the relevant viscoelastic properties. Several hydrodynamic models have been postulated to describe collective orientational fluctuations⁴⁷ and surface undulations¹⁴ in membranes.

4.1 Director Fluctuations

One such model, which has been employed by several groups to interpret transverse relaxation, is based on the concept of director fluctuations.^{12,13,47,48} In liquid crystal terminology, the director $\mathbf{n}$ is defined as the vector describing the orientation of the local phase symmetry axis. It represents the direction of preferred molecular orientation, and in a two-dimensional system such as a membrane may be taken to be normal to the layer surface (see Figure 2). Thermally induced deviations of the director about its average orientation occur, which necessarily modulate the spin interactions of the constituent molecules and hence effect spin relaxation. The director fluctuations may be decomposed into a set of Fourier modes of wavevector q , with mean-square amplitudes $\langle \theta_0^2(q) \rangle$ and exponential decay constants, $\tau(q)$ given by

$$\langle \theta_0^2(q) \rangle = \frac{k_B T}{V K q^2} \quad (9a)$$

$$\tau(q) = \frac{\eta}{K q^2} \quad (9b)$$

where K is an elastic constant, η is an effective viscosity, and V is the volume of the mesoscopic uniform sample. By analogy with models developed for director fluctuations in thermotropic liquid crystals,⁴⁸ K can be identified with the splay elastic constant K_1 , although it has also been suggested that an appropriate quantity for membranes is the curvature elastic modulus $\kappa_c = Kd$, dependent on the bilayer repeat distance d . A more general model for collective motions in membranes, considering bilayer interactions, has been presented recently.⁴⁹

In deriving Equation (9a), it has been assumed that the director fluctuations are of low amplitude. It then follows that the corresponding spectral densities, defined in the average director or local frame, are highly anisotropic in that $J_1^{\text{loc}}(\omega) \gg J_0^{\text{loc}}(\omega)$, $J_2^{\text{loc}}(\omega)$, and, as a first approximation, it is reasonable to retain just $J_1^{\text{loc}}(\omega)$. Combining equations (6) and (7), and replacing the sum over modes l with an integral over the wavevector q , we obtain

$$R_{2E}^{CP} = \frac{27}{8} C \frac{k_B T}{\pi K d} \sin^2 \theta_N \cos^2 \theta_N \times \int_{q_1}^{q_c} \frac{8}{\pi^2} \frac{\tau(q)}{1 + \tau^2(q)(\frac{1}{2}\pi\omega)^2} \hbox{boxd} \ln q \quad (10)$$

The short-wavelength cutoff q_c is governed principally by the molecular dimensions, while the long-wavelength cutoff q_1 is related to the size of the effective uniform sample and therefore reflects mesoscopic dimensions. In the case of magnetic damping of collective modes, the long-wavelength cutoff is determined by the magnetic coherence length $\xi = 1/q_1 = (K\mu_0/\Delta\chi)^{1/2}(1/B_0)|P_2(\cos \theta_N)|^{-1/2}$, where $\Delta\chi$ is the effective diamagnetic susceptibility anisotropy and μ_0 is the absolute magnetic permeability. The Legendre polynomial $P_2(\cos \theta_N)$ accounts for the orientation dependence of the

Table 1 NMR and Viscoelastic Parameters for Biological Model Membranes at $T = 313$ K

Membrane System	Spectral parameter $\Delta\nu$ (kHz)		Elastic constant ^a K (10^{-11} N)		Effective viscosity ^b η (10^{-3} Pa s)
	³¹ P	² H	³¹ P	² H	
Pure DMPC	5.2	3.5	0.65	0.50	3.0
DMPC/4 mol% gramicidin	4.9	4.8	1.1	1.0	3.5
DMPC/40 mol% cholesterol	5.4	11.7	6.0	6.0	8.0

^a K can be identified with the splay elastic constant K_1 .⁴⁷ A related quantity for membranes is the curvature elastic modulus $k_c = Kd$,¹⁴ dependent on the bilayer repeat distance d .

^bThe viscosity η estimated from the low-frequency cutoff ω_l (see text), based on a diamagnetic susceptibility anisotropy of $\Delta\chi = 1.2 \times 10^{-7}$ SI units.⁵¹

magnetic interaction.⁴⁴ Performing the integration in equation (10) gives

$$R_{2E}^{CP} = \begin{cases} A\omega_l^{-1} & (\omega < \omega_l) \\ A\omega^{-1} & (\omega_c < \omega < \omega_l) \\ A\omega_c\omega^{-2} & (\omega > \omega_c) \end{cases} \quad (11)$$

with

$$A = \frac{27}{2\pi^3} C \sin^2 \theta_N \cos^2 \theta_N \frac{k_B T}{Kd} \quad (12)$$

where $\omega_l = Kq_l^2/\eta = \Delta\chi B_0^2 |P_2(\cos \theta_N)|/\mu_0\eta$ is the low-frequency cutoff and $\omega_c = Kq_c^2/\eta$ is the high-frequency cutoff. Thus, in the intermediate dispersion regime, we find that $R_{2E}^{CP} \propto \omega^{-1}$ and is independent of η . In the low-frequency regime, R_{2E}^{CP} depends on both K and η as well as on B_0 .

4.2 Viscoelastic Parameters

The above expressions account at least qualitatively for the results presented in the previous section. The only obvious point of discrepancy between equation (11) and the experimental results is in the predicted divergence of T_{2E}^{CP} at $\theta_N = 0^\circ$ and $\theta_N = 90^\circ$, although both the oriented sample and the multilamellar vesicles were found to exhibit the correct form for the R_{2E}^{CP} anisotropy. A second-order analysis of director fluctuations^{44,50} yields expressions for $J_0^{loc}(\omega)$ and $J_2^{loc}(\omega)$, and consequently predicts finite T_{2E}^{CP} values at all orientations. A slow motional approach also predicts finite T_{2E}^{CP} at 0° and 90° , and is probably more suitable in the present case. However, the detailed modeling of multiple diffusion process such as director fluctuations in the slow motional regime is far from trivial. For present purposes, we restrict our analysis to the first-order motional narrowing limit expressions. By fitting experimental results, the fast relaxation component (45°) yields values for the elastic constant K of the DMPC membranes. From the low-frequency cutoff of the slow relaxation component (90°), estimates for the effective viscosity η are obtained. The results of the analysis are given in Table 1.

The values obtained for K and η are reasonable, and indicate that transverse spin relaxation is able to provide information concerning viscoelastic properties in biological membranes. Of particular importance from a biological point of view is that the technique may be exploited to investigate modifications of membrane viscoelastic behavior caused by included sterols,

peptides, or proteins. Indeed, the results presented in Table 1 suggest that these effects are by no means small, and invite speculation regarding the consequences for overall membrane function.

1 INTRODUCTION

Though crystallographic techniques continue to provide a wealth of protein structural information, the study of conformational changes involved in protein function remains problematic. A protein frequently can only be crystallized in a single conformational state, crystallization may suppress essential dynamics, and crystallography may fail to resolve subtle, but important, conformational changes. Where the protein is too large or the lifetime of a conformational state (e.g. a phosphorylated intermediate) is too short, solution structure determination by multidimensional NMR is not a viable alternative. Fluorine-19 NMR can overcome these problems by providing rapid, sensitive detection of large protein resonances in solution.¹⁻³ The utility of ^{19}F NMR can be augmented by applying it to proteins of known crystal structure, thereby combining the advantages of high-resolution structural information and the ability to observe the behavior of the protein in solution. The ^{19}F NMR studies of the proteins of bacterial chemotaxis⁴⁻¹⁰ represent the first such structure-based application, and the results are being used as a database for the prediction of ^{19}F chemical shifts in proteins (see also *Chemical Shifts in Biochemical Systems*).^{11,12} The power of this approach has been further enhanced by the use of genetic manipulation.

There are several factors contributing to the power of ^{19}F NMR.^{4-10,13,14} (i) The ^{19}F nucleus ($S = \frac{1}{2}$) occurs with 100% natural abundance and has a high sensitivity (83% that of ^1H). (ii) ^{19}F does not occur naturally in proteins, thus there are no background signals with which to contend. (iii) Though the large anisotropy of the chemical shift tensor leads to broader linewidths at high field strengths, the frequency range is large (100-fold larger than ^1H), and individual resonances can generally be resolved. Furthermore, the chemical shift is controlled primarily by the fluorine lone pair electrons, which provide a large paramagnetic term in the shielding formula. As a result, the resonance frequency is exquisitely sensitive to changes in the local van der Waals environment as well as local electrostatic forces.^{11,12} (iv) Fluorine is nearly the same size as hydrogen (covalent radius of 0.014 nm compared with 0.012 nm, respectively), and aromatic fluorine lacks the propensity to form hydrogen bonds.^{13,14} Thus the substitution of fluorine for hydrogen on

an aromatic ring is generally nonperturbing, as confirmed by activity assays.^{3,4,9,10} (v) Fluorine can be easily incorporated biosynthetically. (vi) Fluorine resonances are often resolved in one-dimensional spectra, thus detection requires less time and lower concentrations of protein than multidimensional techniques.

Bacterial chemotaxis provides an ideal model system for conformational studies of signaling proteins. It is a simple, well-defined pathway of the two-component type widespread in prokaryotes and eukaryotes, which has many features in common with other eukaryotic signaling pathways.¹⁵⁻¹⁸ Furthermore, structures have been determined for many of its components. These proteins, being in a bacterial system, are easily genetically manipulated. Chemotaxis proteins which have been studied by ^{19}F NMR include the galactose-binding protein,⁴⁻⁷ the aspartate receptor,^{7,10} and the response regulator, CheY.^{8,9} Briefly, the galactose-binding protein is a 32 kDa periplasmic soluble receptor which binds the attractant galactose or glucose, then docks to and regulates a transmembrane chemoreceptor similar to the aspartate receptor. The transmembrane aspartate receptor is a 120 kDa dimeric protein which directly senses attractants such as aspartate or glutamate in the periplasm and, in response to changes in concentrations of these ligands, alters the activity of an associated cytoplasmic kinase. This kinase transfers a phosphate to the response regulator CheY, a 14 kDa signaling protein which binds to and regulates the flagellar motor, thereby altering the swimming behavior of the cell.

2 METHODS

The fluorine labels of choice are aromatic amino acids containing a single fluorine substituted for hydrogen at a specific ring position. A wide variety of isomers are available. One advantage of these labels is that they can be easily biosynthetically incorporated into the protein by eliminating the ability of the cell to synthesize endogenously the respective amino acid. This is accomplished by using a bacterial strain auxotrophic for the amino acid of interest^{4,8} or by adding glyphosate,¹⁰ which inhibits all three aromatic amino acid synthesis pathways. Subsequently the desired fluorine label is added to the growth medium during protein expression. Less than 100% incorporation is achieved because it is necessary to include unlabeled amino acid in order to maximize protein production. Observed incorporation levels range from 5 to 65%.^{4,8,10}

It is important to determine the effect of fluorine incorporation on protein activity, to ascertain whether the fluorine label is perturbing. Two approaches are used. When high levels of incorporation are achieved, the effect of fluorine on the activity can be assayed directly.⁴ When the level of incorporation is low, a mutagenic approach is required. For instance, in studies using 4-F-Phe, a specific phenylalanine may be replaced with tyrosine to determine the maximum effect of *para* substitution at that location in the protein.^{9,10}

Assignment of resonances is carried out by site-directed mutagenesis. Figure 1 illustrates the two different methods utilized in assignment. The first method generates a conservative substitution at a specific labeling position (e.g. phenylalanine to tyrosine).^{3,4,8,10} When a single resonance disappears, leaving those remaining unaffected, this resonance can be directly

Figure 1 Assignment of 4-F-Phe resonances in CheY.⁸ Shown are ¹⁹F NMR spectra of (a) the wild-type protein, (b) the F14Y mutant used to assign the 4-F-Phe14 resonance by direct replacement, and (c) the N121Q mutant which assigns the 4-F-Phe124 resonance by the “nudge” method. The numbers above the spectra indicate the 4-F-Phe residue to which each resonance has been assigned. The arrows indicate the original position of each altered resonance

Figure 2 Paramagnetic broadening of solvent-exposed resonances by $\text{Gd}^{3+}\text{EDTA}^{4-}$. Shown are the ¹⁹F NMR spectra¹⁰ of the (a) apo and (b) aspartate-bound conformations of the 4-F-Phe-labeled aspartate receptor in the presence (bold line) and absence (fine line) of $\text{Gd}^{3+}\text{EDTA}^{4-}$. The numbers above the spectra indicate the 4-F-Phe positions to which each resonance has been assigned. Bold-face numbers indicate the resonances which have been broadened by the probe. The arrows and diagonal lines indicate resonances which are shifted by aspartate

assigned to the substituted position [Figure 1(b)]. The second approach (termed the ‘nudge’ method) identifies, in the crystal structure, a sidechain which is in van der Waals contact with the position of interest. The contacting side chain is then replaced with a larger or smaller side chain, and, when a single resonance is altered, it can be assigned to the ‘nudged’ position [Figure 1(c)].^{8,10} In most cases, the assignment of a surface residue can be confirmed by paramagnetic broadening,^{8,10} since the resonance of a surface residue should be broadened by an aqueous paramagnetic probe, such as chelated Gd^{3+} (Figure 2).

3 USE OF ¹⁹F NMR TO PROBE CONFORMATIONAL CHANGES

3.1 Strategy

Due to the importance of aromatic side chains in many aspects of protein function, aromatic fluorine labels are often located in critical regions of the target protein, including most ligand and effector protein-binding sites, as indicated in Figure 3. Two ¹⁹F NMR approaches are used to probe conformational changes. The first is to map out the regions involved in the conformational change by observing which ¹⁹F NMR resonances yield chemical shift changes (e.g. Figure 4). Though neither the sign nor the magnitude of a chemical shift change is interpretable, the shift change does indicate a conformational change in the vicinity of the label. In fact, the extreme sensitivity of ¹⁹F NMR resonances to their environment provides what is perhaps the most sensitive physical method available for the detection of local conformational changes. The second technique uses paramagnetic broadening to measure distances and changes in solvent exposure (e.g. Figure 2). The two techniques have been used to characterize conformational changes due to ligand binding, mutagenesis, disulfide formation, phosphorylation, and protein–protein interactions in the following chemotaxis proteins.

3.2 Galactose-Binding Protein

When the galactose-binding protein is labeled at its five tryptophan positions with 5-F-Trp, the ligands D-galactose and D-glucose are observed to induce significantly different chemical shift changes for the 5-F-Trp183 resonance from the sugar-binding site, while inducing identical shift changes for both the 5-F-Trp133 and 5-F-Trp195 resonances, as seen in Figure 4.⁴ In contrast, no shift changes are observed for the 5-F-Trp127 and 5-F-Trp133 resonances from the vicinity of the Ca^{2+} binding site. The converse is observed when Ca^{2+} binds: only the nearby 5-F-Trp127 and 5-F-Trp133 resonances yield detectable shift changes [compare Figure 3(a) and Figure 3(b)].⁵ Similar results are obtained when the protein is labeled at its seven phenylalanine positions with 3-F-Phe.^{4,5} Together these results indicate that sugar binding triggers a long-range conformational change in both domains of the galactose-binding protein, while Ca^{2+} alters only the region near its binding site. The results are consistent with the different functions of these ligands: sugar binding must generate changes in surface structure which enable docking to a transmembrane receptor, while Ca^{2+} binding simply stabilizes the folded structure and does not have a signaling role. The results also demonstrate the ability of ¹⁹F NMR to distinguish local and global conformational changes in the same signaling protein.

A key feature of the conformational change induced by sugar binding is the closure of the sugar-binding cleft, which traps the sugar inside. The minimum angle of cleft opening upon removal of sugar has been measured by paramagnetic broadening using the aqueous probe $\text{Gd}^{3+}\text{EDTA}^{4-}$. This method utilizes the inverse sixth power distance dependence of paramagnetic broadening which quantifies the separation

Figure 3 Use of ^{19}F NMR to map conformational changes in the crystal structures of the galactose-binding protein,¹⁹ the ligand-binding domain of aspartate receptor,²⁰ and the response regulator CheY.²¹ Fluorine-labeling positions are shown as CPK aromatic side chains colored green when the ^{19}F NMR chemical shift is unperturbed by the indicated conformational changes, or red when the chemical shift is perturbed. Thus the red probe residues map out the regions involved in each observed conformational change. (A),(B) Conformational effects of D-glucose (cyan CPK) and Ca^{2+} (yellow sphere) binding to the galactose-binding protein, respectively.^{3,4} (C),(D) Conformational effects of aspartate binding, and either intersubunit disulfide formation or 1,10-phenanthroline binding to the ligand-binding domain of the aspartate receptor, respectively.¹⁰ Also shown are one of the two symmetric aspartate-binding sites (CPK side-chains colored by atom type) and the intersubunit disulfide (CPK side-chain labeled S-S'). (E),(G) Conformational effects of phosphorylation, activating mutations (D13K and D13R), and kinase fragment binding [CheA(P2)] on the response regulator CheY, respectively.^{8,9,24} Also displayed are the conserved active site residues Asp12, Asp13, Asp57, and Lys109 (CPK side chains colored by atom type)

Figure 4 Effect of sugar ligands on the galactose-binding protein.⁴ Shown are the ^{19}F NMR spectra of the (a) apo, (b) D-galactose-bound, and (c) D-glucose-bound conformations of the 5-F-Trp-labeled galactose-binding protein. The numbers above the spectra indicate the 5-F-Trp positions to which the resonances have been assigned. The arrows and diagonal lines indicate resonances which shift upon ligand binding

Figure 5 Determination of the extent of cleft opening in the galactose-binding protein.⁶ The minimum distance (r) between the ^{19}F nucleus of 5-F-Trp183 (F) and the $\text{Gd}^{3+}\text{EDTA}^{4-}$ probe (Gd) is determined by the paramagnetic broadening of the observed NMR resonance. The known dimensions of the cleft and the probe, together with the minimum distance r , enable calculation of the cleft angle

between the paramagnet and the observed ^{19}F nucleus. Due to the mobility of the paramagnet, the linewidth cannot determine the exact separation, but it can establish an upper bound on this distance and thus a minimum angle of cleft opening. The cleft is observed to open at least 18° in the absence of sugar, enabling the paramagnetic probe to enter (Figure 5).⁶

3.3 Aspartate Receptor

In a ^{19}F NMR study of the 5-F-Trp-labeled aspartate receptor in its native membrane, the resonance of a lone, mobile 5-F-Trp residue in the cytoplasmic domain near the C-terminus is detected.⁷ Aspartate binding to the periplasmic domain on the opposite side of the membrane generates a transmembrane conformational transition yielding a chemical shift change for the probe resonance. Multiple probe resonances are needed, however, to map out the regions of the protein involved in transmembrane signaling.

To probe the initiation of the transmembrane signal, the soluble ligand-binding domain of the receptor, which has been cloned and shown to retain the native conformational change,^{10,22} has been investigated. Upon labeling with 4-F-Phe at the six phenylalanine positions in each monomer, ^{19}F

NMR studies of the dimeric domain reveal a broad group of unresolved resonances in the absence of ligand, indicating a dynamic or heterogeneous structure.¹⁰ Introduction of a cysteine mutation and formation of a disulfide bond (Cys36-Cys36') between subunits of the homodimer stabilizes the apo conformation such that resonances become resolved and the effect of ligand binding can be monitored. As seen for the galactose-binding protein, different ligands generate different local conformations in the activation site but the same long-range conformational change [Figure 2 and 3(c)]. Furthermore, since the 4-F-Phe107 residue lies over 1 nm from the subunit interface the aspartate-induced chemical shift change observed for its resonance indicates that a conformational change occurs within each subunit. The 4-F-Phe180 resonance also exhibits an aspartate-induced chemical shift change, as well as an increase in solvent exposure detected by paramagnetic line broadening (see Figure 2). These results imply that the transmembrane signal may be transmitted through the C-terminal helix of the domain, which extends from the Phe180 position across the bilayer as the second transmembrane helix in the intact receptor. Finally, though the dimer contains two identical attractant binding sites, the full conformational change is observed when only one site is occupied, indicating negative cooperativity between the sites.¹⁰

In contrast to the long-range conformational change triggered by aspartate binding to the activation site, introduction of the Cys36-Cys36' disulfide bond or the binding of the nonphysiological ligand 1,10-phenanthroline generates only a local conformational change [see Figure 3(d)].¹⁰ Thus, as for the galactose-binding protein, ^{19}F NMR is able to identify the long-range conformational change specifically generated by an activating ligand.

3.4 CheY

The short lifetime of the phosphorylated state of CheY ($\tau_{1/2} \sim 6$ s) poses considerable difficulties in studies of the activated conformation by NMR. This problem has been overcome by chemically phosphorylating CheY with small-molecule phosphodonors such as acetyl phosphate.²³ Using excess acetyl phosphate to maintain steady state phosphorylation over a period of 10 min, a ^{19}F NMR spectrum has been obtained of 4-F-Phe-labeled CheY-phosphate.⁸ The results indicate that a global conformational change is induced by phosphorylation (see Figure 3(e)).

Investigating the conformational changes induced by six single or double mutations which constitutively activate the protein allows development of a more detailed model for CheY.⁹ The one consistent perturbation caused by these activating mutations is in the chemical shift of the 4-F-Phe111 resonance, which provides a sensitive probe of the salt bridge between Lys 109 and Asp57, the site of phosphorylation in the wild-type protein (see Figure 3(f)). It has been proposed that a repositioning of this salt bridge provides an on-off 'switch' during activation.¹⁴ The chemical shift change of the 4-F-Phe111 probe suggests that the salt bridge is weakened or broken by the activating mutations, thereby supporting the idea that this ionic interaction plays a central role in activation. Other ^{19}F NMR and genetic results indicate that the activation of Che Y occurs in two conformational steps: the first generated by phosphorylation, and the second presumably

Figure 6 Effect of kinase fragment binding on CheY.²⁴ Shown are the ^{19}F NMR spectra of 4-F-Phe-labeled CheY in the (a) absence (apo conformation) and (b) presence of the unlabeled kinase fragment CheA(P2). The numbers above the spectra indicate the 4-F-Phe positions to which each resonance has been assigned. The arrows and diagonal lines indicate resonances which have been shifted by CheA(P2) binding. ^{19}F NMR spectra were obtained as previously described.⁸ Protein concentrations were $[\text{CheY}] = 4 \text{ mM}$ and $[\text{CheA(P2)}] = 6 \text{ mM}$

triggered by docking to its effector complex, the flagellar motor.

A subsequent ^{19}F NMR study of 4-F-Phe-labeled CheY has characterized the region of this protein perturbed by the binding of CheA(P2), a kinase fragment containing the CheY-binding domain (Figure 6).²⁴ Interestingly, the conformational change is localized on the opposite side of CheY from the site of phosphorylation [Figure 3(g)], implying that the kinase domain of CheA must reach around the CheY molecule in order to phosphorylate it.

3.5 Summary of ^{19}F NMR Chemical Shift Changes

Figure 7 summarizes the chemical shift changes triggered by ligand binding, phosphorylation, activating mutations, and disulfide formation in the galactose-binding protein, the aspartate binding domain, and CheY. The largest frequency shifts are observed for fluorine labels within 0.7 nm of the modification site. However, large shifts ($>0.5 \text{ ppm}$) are also observed at label positions ranging up to 1.8 nm from the modification site. These results confirm the ability of ^{19}F NMR to detect both the local changes near a modification site and the long-range conformational changes which play critical roles in the functions of these signaling proteins.

4 USE OF ^{19}F NMR TO PROBE LIGAND-BINDING KINETICS

In addition to providing a spatial map of conformational changes in chemotaxis proteins, ^{19}F NMR has been used to characterize the kinetic parameters of these conformational changes. The standard relationships of NMR exchange averaging can place limits on the frequency of a conformational

Figure 7 Distance dependence of chemical shift changes. Shown is a summary of chemical shift changes induced by ligand binding, phosphorylation, disulfide formation, and lock-on mutations in three chemotaxis proteins. Each chemical shift change is plotted according to its distance from the modification site in the known crystal structure. $\circ$, 5-F-Trp; $\bullet$, 4-F-Phe

change, or, in favorable cases, can determine this rate directly [equations (1)–(3)].²⁵

Slow exchange: distinct resonances

$$(\nu_{\text{ic}} \ll |\nu_{\text{A}} - \nu_{\text{B}}|) \quad (1)$$

Intermediate exchange: resonances disappear

$$(\nu_{\text{ic}} \sim |\nu_{\text{A}} - \nu_{\text{B}}|) \quad (2)$$

Fast exchange: single averaged resonance

$$(\nu_{\text{ic}} \gg |\nu_{\text{A}} - \nu_{\text{B}}|) \quad (3)$$

When two conformations A and B yielding NMR frequencies ν_{A} and ν_{B} interconvert over time at a frequency of ν_{ic} , two distinct resonances are observed if the interconversion is slow relative to the difference in their NMR frequencies (equation (1)). If, on the other hand, the interconversion rate is rapid relative to the NMR frequency difference, then a single exchange-averaged resonance is observed (equation (3)). In the intermediate exchange limit, where the interconversion rate approximately equals the NMR frequency difference, the two resonances disappear due to extreme broadening [equation (2)]. Observation of the latter intermediate exchange limit enables direct determination of the interconversion rate, while the slow and rapid exchange cases provide upper and lower limits, respectively, on the interconversion rate. Spectral simulations can provide further information on both interconversion kinetics and the relative populations of different conformational states.

In the case of the galactose-binding protein, ^{19}F NMR has confirmed the long lifetime of sugar bound in the cleft,⁴ which enables the binding protein to trap a sugar molecule until the complex diffuses to its membrane docking site. The 5-F-Trp183 resonance shifts by 3.8 ppm (1800 Hz) upon addition of D-galactose, and by 2.8 ppm (1300 Hz) upon addition of D-glucose. In either case, addition of substoichiometric amounts of the ligand results in distinct resonances at positions corresponding to the apo and ligand-bound states, indicating

that sugar dissociation is in the slow exchange limit. Thus, from equation (1) it can be concluded that the lifetime of the galactose-bound state $\tau_{ic} \gg 0.6$ ms and the lifetime of the glucose-bound state is $\tau_{ic} \gg 0.8$ ms, consistent with direct kinetic measurements yielding bound sugar lifetimes of 220 ms for D-galactose and 710 ms for D-glucose.²⁶

Turning to the ligand-binding domain of the aspartate receptor, kinetic analysis has revealed the rate constants for both aspartate association and dissociation.¹⁰ When the ligand-binding domain is titrated with increasing concentrations of aspartate, the ¹⁹F NMR resonance of 4-F-Phe150 in the aspartate-binding pocket passes from slow to intermediate to rapid exchange as the rate of aspartate binding increases, due to the interconversion of the apo and aspartate-occupied conformations. At an estimated free aspartate concentration of 0.4 μ M, the intermediate exchange limit is reached and the resonance disappears. From equation (2), this aspartate concentration yields an aspartate-binding rate which matches the frequency difference ($\nu_{ic} = k_{on} \cdot [\text{Asp}] \sim |\nu_A - \nu_B|$), thereby yielding the pseudo-first order rate constant for aspartate binding, $k_{on} \sim 10^9 \text{ M}^{-1} \text{ s}^{-1}$. Subsequently the dissociation rate can be calculated from the association rate constant and $K_D (= k_{off}/k_{on} = 10^{-6} \text{ M})$, yielding $k_{off} \sim 10^3 \text{ s}^{-1}$. (Here the frequency difference $|\nu_A - \nu_B|$ is 1.3 ppm or 610 Hz, as measured at saturating aspartate concentrations. In this example no corrections are needed for population differences, since in the intermediate exchange limit the aspartate association and dissociation rates are nearly equal, so that the apo and aspartate-occupied conformations are equally populated.) These results indicate that aspartate binding approaches the diffusion-controlled limit, placing the aspartate-binding domain in the category of the most rapid protein enzymes in its ability to bind ligands on a short timescale. Moreover, the aspartate binding and dissociation rates are fast on the timescale of the chemotactic response, indicating that subsequent phosphorylation and/or diffusion events are rate-limiting in the signaling pathway.

1 INTRODUCTION

High-resolution NMR spectroscopy has become, alongside X-ray crystallography, one of the two most important physical methods for the study of the *structure, dynamics, interactions* and *function* of biological macromolecules—in particular proteins and nucleic acids and, to a lesser extent, polysaccharides. This article summarizes under each of these headings the general framework, the essential techniques and classical paradigms for the application of NMR in molecular biology, illustrated by the key original findings. More specialized accounts can be found under specific topics. The historical development of this field has been described in volume I of this Encyclopedia.

High-resolution NMR shares a common feature with X-ray diffraction in that both methods—in contrast to all other physical methods—permit the study of biological macromolecules at *atomic resolution*. Beyond that, the two methods are in many ways complementary. NMR offers the advantage that it allows the study of macromolecules in solution, their natural environment, while X-ray diffraction requires crystallization. Structures with molecular weights up to 37 kDa can now be determined by NMR, and the molecular weight range is likely to be soon extended upwards. Structures approaching the 1000 kDa range are already amenable to study by X-ray diffraction. Yet crystallography yields a static picture, whereas NMR provides, in addition to the structure, information on its dynamics. Such information is particularly important for the understanding of biological function. NMR is also the method of choice for the study of ligand interactions. It lends itself more easily to the determination of informative partial structures and allows estimates of ligand exchange rates, rates of structural changes in the macromolecule and observations of the modulation of macromolecular dynamics by ligand binding.

There is, however, a fundamental difference between structural information that can be derived from NMR data and that obtainable by X-ray diffraction. The experimental diffraction pattern is a simple function of geometric parameters and can be converted by Fourier transformation directly into an electron density map and hence, in principle, into a set

of coordinates. In practice, for macromolecular structures, resolution is never sufficient, and model building becomes an essential part of structure determination. On the other hand, direct transformation from data to a set of coordinates is, even in principle, impossible in NMR. Measurable NMR parameters depend simultaneously on several internuclear distances, rates of motion and rates of conformational averaging. To obtain geometric parameters (internuclear distances or angles) from a set of NMR data, it is necessary to make assumptions about the dynamics and other features of the structure. To then obtain a set of coordinates, it is necessary to search the conformational space accessible to the macromolecular chain, usually adding information not obtainable directly from NMR experiments. Both the subjective judgments required and the methods of searching conformational space are important potential sources of error. These are discussed further in the sections devoted to specific methods of structure calculation.

2 MACROMOLECULAR STRUCTURE FROM NMR DATA—GENERAL STRATEGY

Defining the structure and dynamics of a biological macromolecule (protein or nucleic acid fragment) from NMR data requires four steps: (1) experimental *resolution* and (2) *assignment* of the macromolecular spectrum; (3) *interpretation* of the observed spectra in terms of *geometric parameters* and their changes in time; and (4) *structure calculation or model building*, for which a variety of computer algorithms are available.

The limiting steps are usually the resolution and the assignment of the NMR spectrum. NMR spectra of a macromolecule typically consist of a few hundred to a few thousand overlapping lines. The first experimental task is then to resolve all spectral lines and to assign each spectral line to a specific nucleus in a specific residue in the sequence. For linear polymers, such as proteins and nucleic acids (with few exceptions), the task has become manageable. The situation for polysaccharides, where branching is frequent, is more complicated, and the assignment problem has not been completely solved.

The geometric parameters necessary for building models of a macromolecular structure are¹ estimates of internuclear distances, derived from relaxation parameters, in particular from the Nuclear Overhauser Effect (NOE)² estimates of dihedral angles, derived from coupling constants, and auxiliary constraints,³ which can sometimes be derived from chemical shifts (e.g. ring current shifts in nucleic acids, characteristic shifts in α -helices), proton exchange rates (slow rates are often taken to be indicative of hydrogen bonding), or other spectroscopic measurements. NMR spectroscopic data are by themselves never sufficient to define a macromolecular structure. Any structural interpretation of NMR data is, in practice, though not in principle, predicated on prior knowledge of the primary sequence of the macromolecule, of the covalent distances, chirality and bond angles within it and of the van der Waals radii of the constituent atoms.

Model building thus relies on the geometric parameters contained in the known primary structure and on the additional geometric constraints derived from NMR, which play a determining role in the definition of the three-dimensional

folding. It is the only one of the steps that has been largely automated, but it will always require considerable judgment. As will be discussed below, 'calculation' of NMR structures assumes that the structure is rigid. The extent to which this assumption applies varies from one macromolecule to another, and choosing the wrong assumption can lead to a wrong structure.

2.1 Solution Structures of Proteins

Resolution and assignment usually go hand in hand. The specific techniques that can be used at each step of an NMR structure determination differ, depending on the molecular weight of the protein. Simple, purely spectroscopic procedures for obtaining resolution and assignment, applicable to small structures (<10 kDa), break down at higher molecular weights, whereas the more elaborate isotope labeling techniques needed for larger structures are rarely needed for proteins of lower molecular weight.

2.1.1 Resolution

Sufficient resolution of protein NMR spectra to allow their interpretation in atomic detail has become possible by the development of three technologies: (1) high frequency NMR spectrometers, at 500–750 MHz for ^1H , allowing a high degree of chemical shift dispersion; (2) multidimensional (initially two-dimensional) spectroscopy, which allows further separation of lines overlapping in a one-dimensional spectrum by cross peaks to other lines representing physically interacting nuclei; and (3) isotopic spectral editing, or the simplification of protein NMR spectra by prior isotopic (^2H , ^{13}C or ^{15}N) labeling of the protein. As noted, purely spectroscopic methods [(1) and (2)] usually suffice to resolve the spectra of small proteins (<10 kDa). For larger proteins (>20 kDa), isotopic spectral editing is indispensable, and for the intermediate molecular weight range (10–20 kDa), the methodological requirements depend on the extent of overlap of spectral lines, which in turn depends on the specific structure.

The contributions of each of the three technologies to the resolution of protein spectra are best illustrated graphically. Figure 1 compares the one-dimensional spectra of ribonuclease at 40 MHz¹ and 750 MHz. Figure 2 shows the relationship between two-, three-, and four-dimensional spectra.² Figure 3 illustrates the simplification of a two-dimensional proton spectrum by selective deuteration³ and Figure 4 shows the two-dimensional resolution of an overlapping ^1H spectrum by adding a heteronuclear dimension through ^{15}N labeling.⁴ Many multidimensional and isotopic spectral editing schemes are now available. Inasmuch as they not only improve resolution but also allow different assignment strategies, they are discussed below under assignment.

2.1.2 Assignment. Sequential Assignment Methods

The basic idea underlying all *sequential assignment methods* is to establish a connectivity between the spectrum of an amino acid residue with that of its sequential neighbors. Two types of connectivities are generally observable in NMR spectra: (1) through-bond connectivity reflected in spin–spin coupling, possible only between covalently linked atoms;

Figure 1 (a) Ribonuclease spectra taken at 40 MHz. (Reproduced from M. Saunders, A. Wishnia and J. G. Kirkwood, *J. Am. Chem. Soc.*, 1957, **79**, 3289). (b) Ribonuclease spectra (2 mmol double-labeled RNase in 90% $\text{H}_2\text{O}/10\%$ D_2O , ^1H NOESY, 16 scans) taken at 750 MHz. (Courtesy of Bruker Instruments, Inc.)

and (2) through-space connectivity reflected in relaxation parameters—in particular the NOE, i.e. the connectivity between any two atoms in spatial proximity. Either can be used for sequential assignment, and different assignment strategies now use different combinations of either or both. The classical paradigm for sequential assignment emerged gradually. The use of coupling constants to identify amino acid residues in peptides by residue type was introduced in 1957 in the very first systematic study of amino acid and peptide spectra by Takeda and Jardetzky.⁵ The use of relaxation parameters to evaluate distances in macromolecules was first suggested in 1964.⁶ The usefulness of the combination was first demonstrated in 1976 by Gibbons⁷ on one-dimensional (1D) spectra of the cyclic peptide, gramicidin S. In this paradigm the peptide NH of each residue is identified by its (small, $J \leq 10$ Hz) coupling to the α -CH of the same residue, and the connectivity between the NH group of residue i and the NH and α -CH groups of residue $i \pm 1$ by a NOE. This 'jumps' the peptide bond, across which spin–spin coupling is too small to be useful, with the help of a relaxation parameter. In this manner, it is, in principle, possible to assign the entire spectrum of a protein, beginning with a residue

Figure 2 Illustration of relationships between heteronuclear $^{15}\text{N}/^{13}\text{C}$ -edited two-, three-, and four-dimensional (^{13}C or ^{15}N) NOESY spectra. (Modified from Clore and Gronenborn²)

whose assignment is easily established (e.g. an N- or C-terminal, or with a unique residue in a protein) and then sequentially tracing all connectivities along the polypeptide chain. The Gibbons paradigm is illustrated in Figure 5. The tracing is much more easily done in 2D spectra, where the connectivities are seen directly as cross peaks in the spectrum. Two types of 2D spectra are required as a minimum for this purpose: a COSY-type spectrum to establish through-bond connectivities, thereby at least identifying the side chains; and a NOESY-type spectrum to establish through-space connectivities. For peptides and small proteins studied at 500–600 MHz, stumbling blocks are rare, and a complete assignment of the ^1H spectrum using this paradigm can, as a rule, be obtained. Since other characteristics distances can be defined for specific types of secondary structure (e.g., for the $\text{NH } i \rightarrow \text{NH } i + 3$ for α -helices, or $\text{NH } i \rightarrow \text{NH } i + 2$ for β -sheets), the assignment procedure simultaneously yields the secondary structure pattern of the protein.

Although the paradigm is applicable, in principle, to any polypeptide chain regardless of length, practical limitations preclude its use for larger proteins. For structures larger than 10 kDa the overlap makes it difficult to distinguish between different sequential assignment possibilities and, in addition, at higher molecular weights (15–20 kDa) line broadening is

Figure 3 Comparison of the aliphatic region of (a) the natural abundance or wild-type *trp*-repressor DQF (double quantum filtered) COSY spectrum with (b) the spectrum of selectively deuterated *trp*-repressor analog (A5). (Reproduced from C. H. Arrowsmith, L. Treat Clemons, L. Szilágyi, R. Pachter and O. Jardetzky, *Makromol. Chem., Macromol. Symp.*, 1990, **34**, 33)

usually sufficient to obliterate most $\text{NH}-\alpha\text{-CH}$ couplings. A scheme based entirely on NOEs along the peptide chain and a combination of coupling constants and NOEs within side chains can sometimes be used instead.⁸ However, for unedited spectra the usefulness of this technique is still limited by overlap: increasing overlap with increasing molecular weight leads to exponentially growing ambiguities in following the sequence. Therefore, for larger molecules, isotopic spectral editing is required for both resolution and assignment.

Isotopic Spectral Editing in its simplest form, as proposed by us in 1965, is achieved by selective deuteration. Biosynthesis of proteins from a mixture of deuterated and protonated amino acids allows the preparation of a series of labeled

Figure 4 (a) Two-dimensional homonuclear spectrum of *trp*-repressor. (b) The ^{15}N -labeled HMQC spectrum of the same region of the *trp*-repressor

Figure 5 Gibbons's paradigm: magnetization transfer pathways and scalar connectivities in the peptide backbone. Arrows denote distances from the amide proton that can be defined. (Reproduced from O. Jardetzky, A. Lane, J.-F. Lefèvre, O. Lichtarge, B. Hayes-Roth, and B. Buchanan, in 'NMR in the Life Sciences', eds. E. M. Bradbury and C. Nicolini, Plenum, New York, 1986, pp. 49–72)

analogues in which only the desired combinations of amino acids remain visible to ^1H spectroscopy. Even though the labeling is by residue type (e.g. all leucines protonated, or all isoleucines deuterated), this type of editing reduces the problems of overlap sufficiently to allow, by itself, complete sequential assignment in larger proteins. Its largest drawback is the expense of preparing a sufficient number of deuterated analogues. Selective deuteration also narrows the linewidths by reducing the number of interacting neighbors and hence the number of alternative pathways for magnetization transfer or 'spin diffusion'. This may in some cases allow the observation of coupling constants not observable in a fully protonated

species and the use of such constants for sequential assignment. In other cases, however, line broadening by the nearest neighbor will be sufficient to limit the assignment options to those relying on through-space (NOE) connectivities.

Heteronuclear spectral editing schemes for resolution and assignment using multidimensional spectroscopy based on uniform ^{15}N or combined ^{15}N and ^{13}C labeling have been devised, and their usefulness for assigning the spectra of proteins in the intermediate molecular weight range (20–30 kDa) has been demonstrated. The simplest among these are heteronuclear three-dimensional 3D HMQC (heteronuclear multiple quantum coherence)-NOESY or HSQC (heteronuclear single quantum coherence)-NOESY experiments on uniformly ^{15}N labeled peptide chains. In this experiment, the backbone NH resonances are spread out in two dimensions (^1H and ^{15}N) and their connectivities to each other and to their respective side chains are established by a NOESY experiment in an additional (^1H) dimension. In favorable cases the overlap is reduced sufficiently to allow a complete, or nearly complete, set of sequential assignments needed for a structure determination. At higher molecular weights, however, this is not always sufficient to eliminate overlap, and selective labeling becomes necessary.

A very general triple-resonance sequential assignment strategy based on ^{13}C and ^{15}N double labeling of the peptide chain has been developed.^{9,10} The connectivities that can be established using this strategy, and the 3D experiments required for this purpose are summarized in Figure 6.^{9,11} The crucial interresidue connectivity bridging the peptide bond can be obtained in several different ways, relying on each of the following correlations: (1) HNCO relying on the across-the-amide bond ^{13}CO – ^{15}N coupling $J(\text{NCO}) \approx 15$ Hz; (2) HNCA identifying each NH with the $\text{C}\alpha$ of its side chain by the ^{15}N – $^{13}\text{C}\alpha$ coupling constant $J(\text{NC}\alpha) \approx 7$ – 11 Hz; (3) HCACO identifying each carbonyl with the $\text{C}\alpha$ of its side chain by the large $^{13}\text{C}\alpha$ – ^{13}CO coupling constant $J(\text{C}\alpha\text{CO}) \approx 55$ Hz; (4) ^{15}N HOHAHA-HMQC providing the same identification of the ^{15}NH group with its side chain as (2), but relying on proton couplings, $J(\text{NC}\alpha\text{H}) \approx 5$ – 10 Hz; and (5) HCA(CO)N, again bridging the peptide bond using the two-bond $^{13}\text{C}\alpha(i+1)$ – $^{15}\text{N}(i)$ constant $J(\text{C}\alpha\text{N}) \leq 7$ Hz.

Additional and alternative correlation pathways for the triple resonance correlations can also be defined, and the technique has been successfully used to establish the structures of calmodulin and of its complex with a 2 kDa calmodulin receptor binding domain (16.7 kDa; 19.4 kDa in the complex),¹² the ribonuclease domain of HIV-reverse transcriptase (18 kDa),¹³ *Escherichia coli* enzyme III(glc) (18.1 kDa),¹⁴ and human interleukin-4 (15.4 kDa).¹⁵ The details of these and many other possible similar experiments are described in more detail elsewhere in this Encyclopedia. Although they are very useful extensions of the existing technology for the study of intermediate-size proteins (up to 30 kDa), as a class the heteronuclear multidimensional assignment strategies do not escape the problems posed by increasing molecular weight, for two reasons. First, they require relatively long pulse sequences, which lower the sensitivity of the NMR experiment, and as the T_2 becomes shorter with increasing molecular weight, this effect becomes more prominent. Second, they rely on heteronuclear coupling constants of the order of 10–15 Hz, and in a fully protonated protein at molecular weights above the range 30–40 kDa most of these will be obliterated by line

Figure 6 Connectivities observed in the five different types of three-dimensional NMR experiments. (a) The HNCO experiment correlates the peptide bond C' and ^{15}N resonances with the NH chemical shift. (b) The HNCA experiment correlates the NH and ^{15}N shifts with the intrasidue $\text{C}-\alpha$ shift. For $\approx 60\%$ of the residues in calmodulin, a two-bond connectivity to the $\text{C}-\alpha$ resonance of the preceding residue is also observed (broken line). (c) The HCACO experiment correlates intrasidue $\text{H}-\alpha$, $\text{C}-\alpha$, and C' chemical shifts. (d) The ^{15}N HOHAHA-HMQC experiment correlates intrasidue ^{15}N , NH and $\text{H}-\alpha$ shifts. (e) The HCA(CO)N experiment correlates the $\text{H}-\alpha$ and $\text{C}-\alpha$ shifts of one residue with the ^{15}N shift of the next residue. (Reproduced from M. Ikura, L. E. Kay and A. Bax, *Biochemistry*, 1990, **29**, 4659)

broadening. Their usefulness can be extended by combination with selective deuteration, and the combination has been used successfully in the determination of the structure of the *trp*-repressor–DNA complex (37 kDa).¹⁶ It can be expected that the very significant reduction of the relaxation rate in selectively deuterated proteins will allow even further extension of the usefulness of the combined homo/heteronuclear labeling methods to achieve complete resolution and assignment for

proteins of still higher molecular weight. At the time of writing, the potential of the combined isotope editing techniques has not yet been fully realized. A more detailed discussion of the possibilities and limitations is available.¹⁷

2.1.3 Interpretation of NMR Data to Obtain Geometric Constraints

The conversion of the experimentally observed parameters (mostly intensities of cross peaks in multidimensional spectra) into geometric parameters that can be used for structure calculation (i.e. internuclear distances and dihedral angles) requires a series of subjective judgments.

The simplest model for obtaining a distance from cross peak intensities in a NOESY spectrum is the well known and widely used ‘two-spin approximation’, relating the observed cross-peak intensity (in this case equal to the cross-relaxation rate) to a single internuclear distance, r :

$$\sigma = \frac{K\tau}{r^6} \quad (1a)$$

where K is a constant and τ is the single (rigid body) correlation time. This equation holds *approximately* for small structures observed at short mixing times. For larger structures (above 15 kDa), equation (1a) does not hold even approximately. Even in the simplest case there exists an uncertainty in the relationship between distance and peak intensity, because the value of τ (the local correlation time of the internuclear vector in question) is unknown. The most commonly made assumption is that the macromolecule is rigid and that the overall rotational tumbling time can be used for all internuclear vectors. As noted, this assumption has proved very useful as a first approximation, even though it generally does not hold. The reason for the success of the assumption, even in some cases where its applicability is doubtful, is that the sixth-power relationship between peak intensity or correlation time and distance substantially reduces the error in the distance that results from an erroneous estimate of either peak intensity or correlation time: an error of a factor of 10 in either of the latter results in only a 46% error in the estimated distance. For the determination of the overall topology such errors can be tolerated. To account for them, as well as for the experimental errors of intensity measurements, it is customary to interpret each observed NOE not in terms of a single distance, but in terms of a distance range. A commonly used classification is into ranges allowed for ‘strong’, ‘medium’, and ‘weak’ NOEs. Many different calibrations of appropriate distance ranges, some differentiating between ‘very strong’ and ‘strong’, and ‘weak’ and ‘very weak’, have now been carried out. It can be said that for the first structure calculation, the differences between them are not significant. A set of typical values is given in Table 1, and the issues are discussed in more detail elsewhere.^{18,19}

Some workers have attempted to reduce the uncertainties of relating observed intensities to distance by using an empirical calibration in the form:

$$r_u^6 = \frac{(\text{NOE})_k}{(\text{NOE})_u} \cdot r_k^6 \quad (1b)$$

where $(\text{NOE})_u$ is the intensity of the NOE for the spin pair at an unknown distance, r_u , and $(\text{NOE})_k$ is the NOE intensity

Table 1 Distance between Residues as Determined by NOE Intensity

NOE Intensity	Distance Range (nm)
Strong	0.18–0.27
Medium	0.18–0.33
Weak	0.18–0.50
Very Weak	0.30–0.60

for a spin pair for which the distance r_k is known. However, the use of this calibration implies strictly that the molecule is rigid and that the two-spin approximation applies. Use of distance *ranges* is equivalent to loosening these constraints in order to take the reality of internal flexibility in proteins at least partially into account. The precision of a calibration is therefore deceptive. Given that differences in local correlation times and the limits of the applicability of equation (1a) are now well known, it is doubtful that distances derived by calibration can be considered accurate. Better accuracy is still achieved by using a reasonable estimate of the allowed distance ranges.

A more significant source of error is the fact that equation (1a) does not hold, except for small structures and mixing times that are too short to obtain good spectra on larger molecules. Under these conditions one must take into account that magnetization transfer during the experiment is not limited to the two spins, but occurs between all neighboring spins in the structure. This phenomenon is known as spin diffusion, and the evolution of magnetization (peak intensity) in the presence of spin diffusion is given by the generalized Bloch equations:

$$\frac{dM_i}{dt} = -\rho_i[M_i - M_i(0)] - \sum_{j \neq i} \sigma_{ij}[M_j - M_j(0)]; i \neq j \quad (2)$$

where ρ_i is the spin–lattice relaxation rate of the i th nucleus, and σ_{ij} is the cross-relaxation rate between the two nuclei i and j , as defined in equation (1a).

To solve the generalized Bloch equations, one obviously has to know already the structure that one is trying to determine. The initial structure calculation therefore *always* has to rely on the assumption that equation (1a) holds as a first approximation. To compensate for the additional (and often substantial) errors resulting from spin diffusion, it is necessary to widen the limits for the distance estimates for purposes of the initial calculations on larger molecules. The effects (and errors) due to spin diffusion can be greatly reduced by selective deuteration of the protein, as noted above. The ultimate molecular weight limit for structure determination by NMR remains to be explored, but given the dramatic reduction of linewidths by selective deuteration, probably lies much higher than originally expected. Good local spectra have now been obtained for structures as large as 150 kDa.²⁰ It must be noted that using the solution of equation (2), or of its equivalent, the relaxation matrix equation for the back-calculation of spectra from an initial structure again usually involves the assumption that the structure is rigid and a single correlation time can be used in the structure calculation. Back-calculation based on this assumption may not significantly increase the accuracy of the structure over the crude initial model—as discussed below. The important point to bear in mind is that the geometric parameters derived from

NMR experiments are always approximate, and the quality of the approximations used is an important determinant of the accuracy of the resulting structure.

The magnitude of the errors that can be introduced by neglecting spin diffusion can be well illustrated by an early model calculation on sperm whale myoglobin.¹⁸ Distances derived from the X-ray structure and a correlation time of 8 ns were used to calculate cross-peak intensities by solving the generalized Bloch equations [equation (2)]. These intensities were then analyzed using equation (1a) and the same correlation time to estimate (apparent) ‘NOE distances’. A plot of the apparent distances versus actual crystallographic distances (Figure 7),¹⁸ indicates that the error in the distances calculated from equation (1a) depends on the details of the surrounding structure and may be as high as $\pm 50\%$ for distances >0.3 nm. Very precise distance calibrations of NOEs on an unknown structure [equation (1a) or equation (1b)] are apt to introduce significant distortions into the calculated structure.²¹

The dihedral angles, which can be derived from coupling constants in COSY-type spectra and used to define the conformations of both the protein backbone and of the side chains, are subject to similar uncertainties. In the presence of free rotation around side-chain bonds, the observed values

Figure 7 Apparent ^1H – ^1H distances calculated from NOEs (r_{NMR}) plotted versus actual crystallographic distances (r_c) for helix 4 of myoglobin. NOE cut-off: 2%. (●) Intramolecular distances; (○) intermolecular distances. (Reproduced from O. Jardetzky and A. N. Lane, in ‘Physics of NMR Spectroscopy in Biology and Medicine,’ ed. B. Maraviglia, Italian Physical Society, North-Holland, Amsterdam, 1988, pp. 267–301)

are averages over several conformations and do not permit a unique interpretation. Dihedral angles are most useful along the backbone, where the rotation is hindered, and stereospecific assignments, e.g. those of individual methylene protons, β -CH' and CH'', are possible. In that case, a unique value of the angle (more precisely, a narrow range of angles allowed by the coupling constant) can often be derived from the Karplus relation.²² Since the coupling constant has a strong dependence on the dihedral angle, experimentally derived angles are powerful constraints in a structure calculation. The largest limitation to their use is the fact that the small coupling constants involved (often <10–15 Hz) become largely unresolvable at molecular weights above 15 kDa. For larger molecules, only broad ranges of dihedral angles, inferred from indirect evidence on the secondary structure, can be used (as relatively loose constraints) in the structure calculation.

It is still best to make the choice of assumptions explicitly, on the basis of prior experience and with additional knowledge of the specific system on which the structure is to be determined, although there is an increasing tendency to make them implicitly in an iterative back-calculation of spectral intensities using one of the several computer programs available for this purpose. The danger of such implicit decision-making is that each program has specific assumptions built into it, of which the user may or may not be aware. Almost all programs are built on the assumption that the protein is rigid (or undergoes only averaging of the first kind, i.e. in a potential well about a single energy minimum, but does not undergo any averaging of the second kind, i.e. between different metastable conformations). This assumption holds reasonably well as a zero-order approximation in many cases, especially for smaller, well chosen globular proteins, but the cases of the *trp*-repressor and several other larger proteins have clearly shown that it is not universally applicable. *There exists no general, universally applicable, set of assumptions for the exact geometric interpretation of spectroscopic parameters in macromolecular spectra.* Obviously, the calculated structure will be wrong if the assumptions made at this step are not appropriate for the molecule under study.

2.1.4 Model Building and the Calculation of Protein Structures

There are several options for defining a three-dimensional structure of a protein from the geometric constraints implied by NMR data. The basic paradigm is straightforward: given the primary sequence (with all covalent bond lengths and angles and van der Waals radii implied by it, which must be determined by other methods and known to begin with), and given a set of distance and angular constraints derived from NMR experiments, as outlined above, find the family of all three-dimensional configurations that satisfy the given set of experimental constraints. The essential step here is to search the conformational space available to the polypeptide chain, selecting only those configurations that are allowed by the NMR constraints. The first 3D structure derived from NMR data, that of the *lac*-repressor headpiece (MW $\approx$ 6 kDa) was built by hand, using Pauling-Corey space-filing models.²³ At the time of writing, several classes of search procedures have been implemented in computer programs and are generally available. A major consideration in choosing the procedure is that the search must be sufficiently representative to ascertain

that alternative configurations equally compatible with the experimental data set are included in the final result. This is more easily said than done. The conformational space available to a polypeptide chain is very large (for the two Ramachandran angles, each allowed only two values, it is of the order of 2^{2N} , where N is the number of amino acid residues in the chain; i.e. for 100 residues, it is of the order of 2^{200} or 10^{60}). A systematic search of all possible configurations is therefore computationally out of the question. Even exhaustive random sampling, starting with a variety of randomly chosen arbitrary configurations, is possible only for relatively short peptide chains (up to 10–12 kDa). Consequently, all search procedures have to rely on approximations and it remains important to ascertain that the approximations made in each applicable algorithm are valid for the specific system under investigation. The derivation of three-dimensional structures from NMR data is only possible because some of the experimental distance constraints—in particular NOE constraints between residues distant in the primary sequence (e.g. between residues 6 and 42, or 24 and 98)—at once eliminate large segments of the conformational space. Furthermore, a not very large number of imprecise constraints can define the folding of a polypeptide chain rather accurately, as originally pointed out by Kuntz and coworkers.²⁴ The human mind remains by far the most efficient instrument for recognizing and applying this hierarchy of constraints in order to reduce the search space. For this reason, model building, which had at first been all but abandoned in favor of 'more objective' search procedures that treat all constraints alike, is again gaining in importance as the molecular size of the structures being determined increases, making 'objective' random searches computationally intractable.

Among the available algorithms for searching conformational space and selecting structures compatible with the experimental constraints, it is useful to distinguish between methods that (a) rely on geometric information alone, and (b) those that bring to bear additional information on the search in the form of energy potentials. In the first category of purely geometric methods, there are three classes of algorithms: (1) computer model building, (2) distance geometry, and (3) optimal filtering. In the second category—there is one class: (4) restrained molecular dynamics (RMD). In practice, a combination of a geometric and a dynamic method²⁵ is now almost universally used, and molecular dynamics can be considered indispensable for the refinement of NMR as well as of X-ray structures. At the same time, molecular dynamics is most effective if a starting structure not very far from the final structure is provided. Only for rather small structures is it practical to fold a random polypeptide chain into its final configuration by using an RMD algorithm.

(1) *Computer model building* programs are either entirely manual (e.g. Frodo, Quanta, and MacImDad) or have a built-in routine for conformational-space searches under geometric constraints (e.g. PROTEAN). In the manual programs, the application of covalent, bond angle and van der Waals constraints is often automated, but the application of NMR-derived distance and angular constraints is under the complete control of the experimenter. Application of constraints is usually sequential, with those deemed most constraining (i.e. those connecting two structures, as in the case of protein–DNA complexes, or two distant parts of a protein chain) being applied first. Even though the procedure is subjective, it

is generally valid because all conformations violating these key constraints can be ruled out. As in all initial model building, the assumption is made that averaging between two or more distinct conformations (averaging of the second kind) does not occur. The typical result is a topologically accurate, but imprecise, model that can be used as a starting structure for refinement by RMD. In the case of constraint satisfaction programs, such as PROTEAN, which build models automatically under a given set of constraints, a *systematic* search of the space available for the mutual positioning of units of secondary structure is possible. By considering each unit of secondary structure as a rigid entity and representing it at a higher level of geometrical abstraction (e.g. cylinders for α -helices or β -strands), the number of conformational variables is reduced to a manageable size. This makes a systematic search of the conformational space available to define the main topological features (with the reduced set of key variables) computationally tractable. Since the space to be searched grows exponentially with the number of variables (e.g. rotatable bonds), systematic sampling of conformational space using the complete set of variables is otherwise only possible for very small peptides. If the output of such a systematic search, which generally defines the overall topology rather well, is used as a set of starting structures for molecular-dynamic refinement at atomic resolution, it is possible to minimize the danger of having the refined structure represent a single local minimum. This is difficult, if not impossible, when only a smaller set of starting structures is used, whether such a set is derived from manual model building or random sampling by distance geometry. Adequate sampling of random structures is at present limited to proteins smaller than ~ 12 kDa. For larger structures, random sampling that could safely be considered extensive enough is prohibitively expensive in computer time, and the danger that the reported structure represents only a local minimum remains ever present. Computer model building is hardly necessary for the smaller structures where adequate random sampling is computationally feasible. For larger structures, some degree of preliminary model building is unavoidable. A typical PROTEAN output, defining the topology of the helix–turn–helix *lac*-repressor DNA binding domain (headpiece), along with the uncertainty in the positioning of the different units of secondary structure, is shown in Figure 8.²⁶

(2) *Distance geometry* (DG)²⁷ is a general method for calculating the atomic coordinates of a structure from an arbitrary set of internal distance and/or angular constraints. It has two highly attractive characteristics: (1) it is a simple and rigorous mathematical theory containing the proof that if all the distances between all points within a structure are known precisely, an exact calculation of the coordinates of each point in the structure is possible; and (2) computational efficiency. In applications to NMR structure determination—where only a fraction of all distances that rigorously define the structure can be obtained experimentally—theoretical rigor is lost, but the efficiency of the method for randomly searching conformational space remains.

The input to a DG calculation is: the *distance matrix* derived from experiment—in principle the square matrix of $N(N - 1)/2$ distances between all N atoms (points), in practice a (usually asymmetric) matrix of the distances available from experiment; and an *initial coordinate matrix*, preferably consisting of a random arrangement of points.

Figure 8 *Lac*-Repressor headpiece structure calculated by PROTEAN, showing the uncertainty in the positioning of the different units of secondary structure. (Reproduced from R. B. Altman and O. Jardetzky, *J. Biochem.*, 1986, **100**, 1403)

This represents the ‘starting structure’ for the search of the conformational space. The first step in a DG calculation, called *embedding*, calculates a set of coordinates that represents a multidimensional best fit of the coordinates to all the distances considered simultaneously. As allowed distance ranges rather than precise distances have to be used, and because the number of observable distances is too small to define the structure precisely, the resulting structures that at first seem to satisfy the constraints in fact usually contain a large number of constraint violations—and also violate constraints at first not considered, such as van der Waals radii. A second *optimization* step is therefore necessary to minimize the errors by iterative adjustments, using a scoring function that reflects the number and severity of the violations as a criterion for the goodness of fit.

There are many different algorithms for carrying out the embedding step and many different formulations of the optimization function, a detailed description of which is beyond the scope of this article, but can be found elsewhere.²⁸ The essential mathematical features of the two steps are given by equations (3) and (4). In the first step

$$\mathbf{S} = \lambda \mathbf{M} \quad (3a)$$

where $\mathbf{S}$ is the coordinate matrix and $\mathbf{M}$ is the metric (distance) matrix, calculated from the initially set up distance matrix by a coordinate transformation to refer all distances to the geometric center of the structure which can be calculated from the distance matrix. The elements of $\mathbf{M}$ are:

$$M_{ij} = \frac{1}{2}(D_{i0}^2 + D_{j0}^2 - D_{ij}^2) \quad (3b)$$

where D_{i0} is the distance of the atom i from the origin and D_{ij} the internuclear distance between i and j . λ is the matrix of coefficients relating the two.

The embedding process itself is thus seen from equation (3a) to be an eigenvalue problem (finding the values of λ to yield the values of $\mathbf{S}$), for the solution of which a variety of techniques is available.²⁹ A typical error function useful for

Figure 9 C- α traces of a family of crambin structures computed using the distance geometry protocol. The target structure is shown in green. (Reproduced from J. C. Hoch and A. S. Stern, *J. Biomol. NMR*, 1992, 2, 535)

optimization in distance space is:

$$F_E(R) = \sum_{i < j} (|R_{ij}| - U_{ij})^2 + \sum_{k < l} (L_{kl} - |R_{kl}|)^2 \quad (4)$$

where $F_E(R)$ is the distance error, L_{ij} and U_{ij} the lower and upper distance boundaries, respectively, and R_{ij} the actual distance in the proposed structure. Similar error functions can be introduced for dihedral angles and chiral constraints (to distinguish between L- and D-amino acid configurations). The result of each calculation is a single optimized structure. Experience shows that repeated calculations with the same set of initial constraints but different starting structures do not exactly reproduce the same structure. Therefore, a family of structures is usually obtained by repeated runs of the DG algorithm. Published structure determinations report anywhere from 30 to over 100 closely related but different structures, and the precision of the structure can be measured by taking the root-mean-square deviation (RMSD) of the individual atomic coordinates. A typical family of structures calculated by repeated optimization using a DG algorithm is shown in Figure 9.³⁰

Important to note is that all non systematic search procedures contain several potential sources of bias. Among the most important in the case of DG are: (1) the algorithms used for the generation of starting structures; (2) the adequacy of their use in an individual case; and (3) the choice of weighting factors for the error function when forms more complex than equation (6) are chosen, as they now usually are. Comparisons of different programs are therefore of utmost importance, but thus far have been carried out only sporadically, as discussed below.

(3) *Optimal filtering* is a probabilistic method widely used in signal processing. Its application to the search of conformational space in the course of an NMR structure determination has the advantage that a set of coordinates, and the uncertainty limits of each coordinate, can be obtained in a single calculation from the starting set of distance and angular constraints and the estimated uncertainties of these constraints. This eliminates the need for repeated optimization runs with different starting structures and the bias potentially introduced

by limiting the calculation to an inadequate number of runs. All data relevant to the uncertainty of the final structure are introduced into the calculation and used throughout the calculation at once.

The principle of the method is to represent the system (structure) by a coordinate ‘state vector’ of length $3N$, where N is the number of atoms in the structure, and of the form:

$$\mathbf{x} = [x_1 \ y_1 \ z_1 \ x_2 \ y_2 \ z_2 \ x_3 \ y_3 \ z_3 \ \dots] \quad (5)$$

x_1, y_1, z_1 , etc., denote the x, y, z coordinates of all individual atoms. The uncertainty of the structure is contained in the covariance matrix of $\mathbf{x}$:

$$\mathbf{C}(\mathbf{x}) = \begin{bmatrix} \mathbf{C}(x_{1,1}) & \mathbf{C}(x_{1,2}) & \dots & \mathbf{C}(x_{1,N}) \\ \mathbf{C}(x_{2,1}) & \mathbf{C}(x_{2,2}) & & \\ \vdots & & \ddots & \vdots \\ \mathbf{C}(x_{N,1}) & \dots & & \mathbf{C}(x_{N,N}) \end{bmatrix} \quad (6a)$$

where

$$\mathbf{C}(x_{i,j}) = \begin{bmatrix} \sigma_{x_i x_j} & \sigma_{x_i y_j} & \sigma_{x_i z_j} \\ \sigma_{y_i x_j} & \sigma_{y_i y_j} & \sigma_{y_i z_j} \\ \sigma_{z_i x_j} & \sigma_{z_i y_j} & \sigma_{z_i z_j} \end{bmatrix} \quad (6b)$$

is the covariance matrix for an individual atom with the variance $\sigma_{xy} = E_{(xy)} - E_{(x)}E_{(y)}$ is defined as usual in terms of the expectation values. The diagonal terms of equation (6b) measure the uncertainty in each coordinate, and the off-diagonal terms determine the shape of the spatial distribution of the uncertainty. A common assumption is that this distribution is normal, in which case the uncertainty in the position is given by an ellipsoid. However, asymmetry in the uncertainty distribution of the initial constraints can be taken into account by the use of higher order moments to describe the distribution.

In the first order calculation, distance constraints are used in the form

$$z = |x_i - x_j| + v, \text{ or, generally, } z = h(\mathbf{x}) + v \quad (7)$$

where v is the uncertainty range in the measurement of the distance. A similar equation applies to angular constraints.

The constraints are introduced to update an initial structure given by an initial state vector $\mathbf{x}_0$ to a new structure that better fits the constraints by calculating a new set of coordinates from the Kalman filter formula:

$$\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{old}} + \mathbf{K}[z - h(\mathbf{x}_{\text{old}})] \quad (8)$$

where

$$\mathbf{K} = \mathbf{C}(\mathbf{x}_{\text{old}}) \mathbf{H}^T [\mathbf{H} \mathbf{C}(\mathbf{x}_{\text{old}}) \mathbf{H}^T + \mathbf{C}(v)]^{-1} \quad (9)$$

where T denotes the transpose and $\mathbf{H}$ is given by:

$$\mathbf{H} = \frac{\partial h(\mathbf{x})}{\partial \mathbf{x}} |_{\mathbf{x}_{\text{old}}} \quad (10)$$

Figure 10 Tertiary structure of the *trp*-holorepressor calculated using the Kalman filter. The α -carbon trace is displayed (at 2 SD) with ellipsoids of uncertainty for each α -carbon, the larger ellipsoids at the extreme left and right indicating the larger uncertainty for region D. (Reproduced from C. Arrowsmith, R. Pachter, R. Altman and O. Jardetzky, *Eur. J. Biochem.*, 1991, **202**, 53)

The covariance matrix $\mathbf{C}$ is updated by a formula analogous to equation ((8)). Programs have been written for either a sequential or a simultaneous introduction of constraints, and for calculations in either cartesian (PROTEAN2)³¹ or dihedral angle space (FILMAN).³² The calculation must be iterated for nonlinear systems, hence the occasionally used name, ‘Doubly Iterated Kalman Filter’ (DIKF). As in the case of DG, for small structures the initial ‘structure’ can be a random distribution of points (or all points placed at the origin) with very large initial variances. In both cases, starting structures more closely resembling the final result (and obtained by initial model building) are required for larger proteins to make the structure calculation feasible computationally. Also, in both cases, the definition of the uncertainty in the distance constraints used for the conformational space search remains subjective, as discussed in the section on the conversion of spectral intensities into distances. The topology of the *trp*-repressor backbone, determined by optimal filtering, together with the uncertainty ellipsoids of the α -carbon atoms is shown in Figure 10.³³

The model-building methods described thus far rely on purely geometric information. Because the geometric constraints derived from NMR experiments are generally imprecise and too few in number to give an exact definition of the protein structure, the resulting structures generally represent the overall topology rather well, but contain numerous energetically unfavorable, and sometimes impossible, features. For this reason, refinement of the crude structure by energy minimization is generally necessary, and molecular dynamics algorithms have become the method of choice for this purpose.

(4) *Molecular dynamics*, as a method for search of the conformational space under a given set of geometric constraints, differs from the purely geometric methods of model building, distance geometry and optimal filtering in that energy potentials, representing both attractive and repulsive interactions between atoms, are introduced into the calculation in addition to the experimental constraints.

The technique is based on the solution of Newton’s equations of motion for all atoms in the structure simultaneously:

$$\frac{\partial^2 \mathbf{r}_i}{\partial t^2} = \frac{\partial \mathbf{v}_i}{\partial t} = \frac{\nabla E(\mathbf{r}_i)}{m_i} \quad (11)$$

where $\partial^2 \mathbf{r}_i / \partial t^2$ is the acceleration and $\mathbf{v}_i$ is the velocity of atom i . This mass, m_i , of each atom is known. The force is taken to be the gradient of an empirically defined set of potentials, which is the weighted sum of all relevant terms:

$$E_{(xi)\text{empirical}} = \sum_{P=1}^N N_1 E_{\text{bond}} + w_2^P E_{\text{angle}} + w_3^P E_{\text{dihedral}} + w_4^P E_{\text{van der Waals}} + w_5^P E_{\text{electrostatic}} + w_6^P E_{\text{H bond}} \quad (12)$$

In *restrained molecular dynamics* (RMD), experimental distance and angular constraints are usually introduced as pseudopotentials of the form

$$E_{\text{NOE}} = S \frac{kT}{2d^2} (R - d)^2 \quad (13)$$

where S is a scaling factor, k is the Boltzmann constant, T is the absolute temperature, R is the averaged internuclear distance, and d is the allowed distance bounds.

The solution of Newton’s equations proceeds by numerical integration over very small time steps, Δt , over which the forces are assumed to remain constant:

$$\mathbf{r}_{n+1} = 2\mathbf{r}_n - \mathbf{r}_{n-1} - \frac{\nabla_{\mathbf{r}_n} E(\mathbf{r}_n)}{m} \Delta t^2$$

$$\mathbf{V}_n = \frac{1}{2\Delta t} (\mathbf{r}_{n+1} - \mathbf{r}_{n-1}) \quad (14)$$

This is the so-called *Verlet algorithm*. The choice of a sufficiently small time step (by comparison to the timescale of the fastest motion in the system) is critical, and values of the order of $\Delta t = 0.001$ – 0.002 ps are normally used.

A large amount of literature exists on the best choice of potentials, number of terms and weighting factors,^{34–36} and different programs incorporate sometimes very different sets of potentials. Similarly, the choice of initial velocities, usually based on a Maxwell distribution at a chosen temperature, can be made at will. Both an energy minimum and a trajectory for the motions of individual atoms over the period of the calculation can be calculated for any starting structure.

It is possible to use RMD as a purely geometric method for the search of the conformational space by assigning very high values to the pseudopotentials representing the experimental constraints and making all other potentials negligible by comparison. As in the case of DG and DIKF, the topology of small structures can be calculated successfully by starting with an arbitrary arrangement of atoms (usually given the correct covalent and bond angle constraints). As

the molecular size increases, it rapidly becomes necessary to start with a structure resembling the final result if the computational time is to be kept within manageable limits. This is much more important for RMD than for DG or DIKF calculations because of the larger number of arbitrarily adjustable parameters. The large number of adjustable parameters also makes the method subject to stronger built-in systematic bias. Fortunately, several programs have been tested extensively—notably X-PLOR, CHARMM, GROMOS and AMBER—and even though none of these are fool-proof or free of all bias, internally consistent results can be obtained in most cases. Credible refinement of NMR structures to an ‘effective resolution’, i.e. precision of 0.05 nm, is possible in many cases. This ‘resolution’ is obtained, as in the case of DG, by calculating a family of structures, each representing a complete RMD calculation beginning with a different starting structure each time, and then determining the RMSDs of the atomic coordinates within the family. Of particular interest for structure calculations using molecular dynamics is the simulated annealing protocol (sometimes even discussed as a separate method of structure calculation). In this protocol the temperature is repeatedly raised in the course of each molecular dynamics simulation, in order to reduce systematic bias by randomizing the structure, and then allowed to converge onto a new configuration. For the largest structures refined thus far (37 kDa), the computer time required for the calculation of an RMD family by this procedure can be prohibitively long. For such structures, however, it is possible to invoke the ergodic theorem (equality of the time average to the ensemble average) and use the Sequential simulated annealing protocol³⁷ to obtain a family of structures from a single calculation. A typical family of structures obtained by RMD has the same appearance as a family calculated by DG (see Figure 9).

2.1.5 Back-Calculation of NMR Spectra

Back-calculation of NMR spectra from a given structure has long been recognized as a desirable step for the validation and refinement of the proposed structure,³⁸ regardless of the method initially used to derive the structure. The back-calculation for NOESY-type spectra is based on the numerical integration of the set of generalized Bloch equations [equation (2)] or, as an equivalent, the inversion of the relaxation matrix^{37,39} using the coordinates of the proposed structure to calculate the required interproton distances.^{40,41} Several programs—including BLOCH, CORMA, IRMA, MARDIGRAS—are available for this purpose. Direct refinement of the structure against experimental NOE intensities has also been developed and implemented in X-PLOR. The use of time-averaged distances, with the averaging based on a molecular dynamics trajectory, has been suggested as an improvement to the accuracy of such calculations.⁴² Iterative protocols are part of most suggested procedures. Back-calculation and its applications to both protein and nucleic acid structures are described elsewhere in this Encyclopedia. Of importance in the general context is the fact that a completely correct back-calculation is not possible without detailed knowledge of the spectral density functions (correlation times) needed to describe internal motions in the

protein. Good predictions of spectra from proposed structures are possible when the structure can be taken as rigid and the spectral density functions to be the same throughout the molecule. Unfortunately, spurious agreement between calculated and observed spectra can also occur. In an iterative calculation based on inaccurate (or even wrong) values of the spectral density function, the internuclear distances (and hence the coordinates) can be adjusted until ‘the best fit’ is obtained, even though the adjusted distances would give poor agreement, and hence be judged incorrect, if correct values of the spectral density function were known. The use of time-averaged distances in the back-calculation is also not unproblematic, since molecular dynamics simulations generate predominantly averages of the first kind (around a single major energy minimum), with major conformational averaging being largely left out. With the inherent imprecision of the data, the indeterminacy of the generalized Bloch equations, and the limitations of the proposed remedies of this indeterminacy, the observation has been made on several occasions that back-calculation with existing methods does not significantly improve the ‘quality’ of the reported structures.⁴³ Although a completely rigorous test of this observation is lacking, the observation is likely to remain correct, unless, or until, back-calculations using a correct set of spectral density functions become possible and the obtainable raw NMR data become more precise.

2.1.6 Accuracy and Precision of Protein Structures Determined by NMR

Given the uncertainties and potential sources of bias in each exploration of the conformational space, with each method and each program potentially subject to its own limitations and bias, the use of combined search methods has gained wide popularity. Particularly common are protocols combining DG and RMD into a single program package (e.g. DIANA and DADAS) and those combining either DG or RMD structure calculations with the back-calculation of spectra. It is thought that the bias of each of the constituent search methods will be canceled by the other. The possibility that the errors will be additive has, regrettably, not been properly tested.

Before it becomes possible to assess the validity of individual structures calculated by any particular method or combination of methods, it is necessary to evaluate the *accuracy*, as well as the *precision*, of NMR structure calculations by a comparison of the families of structures calculated by different methods. Accuracy, in this as in other contexts, means the faithfulness of the reproduction of the ‘true’ structure and is only measurable with respect to a ‘gold standard’, i.e. a structure independently determined by another method. Precision, in its usual definition, measures the reproducibility of repeated measurements or calculations. Most of the NMR literature published to date is confused on this issue, and all too often one sees measures of precision offered as a measure of accuracy. The ‘first-order answer’—that protein structures built from NMR constraints, by whatever method, rather faithfully reproduce the main topological features of a protein molecule—can be considered to have been demonstrated beyond any doubt. An exact answer with regard to how accurate NMR structures are is more difficult to give. Only a few rigorous comparisons of the accuracy of NMR structures calculated by different methods have been made thus far.^{21,44} The principal finding is that the mean

structures calculated by different methods from the same set of data differ by an RMSD of 0.1–0.2 nm from each other and from a ‘true’ structure independently determined by X-ray diffraction. Claims that an accuracy of 0.025 nm can be achieved for NMR structures⁴⁵ were not based on a rigorous study of accuracy, but on a comparison of the relative precision of structures calculated by the same method using two different protocols. In such a procedure, the reference (‘true’) structure and the test structures are subject to the same systematic error. The calculated estimates are still estimates of precision and not of accuracy, and the claim is therefore not valid. The accuracy of NMR structures determined by now existing methods cannot be taken to be higher than 0.1–0.2 nm, although the precision of the family of structures calculated by any one method can be considerably higher (of the order of 0.03–0.05 nm). If one remembers that proteins in solution are subject to Brownian and internal motions, it is not too surprising that the family of structures reflected in the NMR data may be appreciably larger than any one particular structure calculation may show.

2.2 Solution Structures of Nucleic Acids

These can be defined by using the same procedures as for the structures of proteins. The structure determination involves the same four steps: resolution and assignment of the spectrum, derivation of geometric parameters from spectroscopic data, and model building. For reasons of resolution, limited by spectral overlap, the possibilities of NMR structure determination are for the present limited to relatively short stretches of oligonucleotides (up to 20–30 mers for double-stranded DNA). For such structures an additional serious limitation comes into play in that only short-range distances, i.e. between adjacent bases and base pairs, can be found. Long range interactions, so useful in defining the tertiary fold of a polypeptide chain, are not found in the short, rod-like structures. It is conceivable that for larger circular and supercoiled DNAs, where long-range interactions occur, they could also be detected and used, as in the case of polypeptides to define the tertiary structure. However, the resolution of the spectra of larger DNA structures is beyond the limits of current methodology. Thus only local structural features in nucleic acids—for di- or trinucleotide stretches—can, for the present, be studied by NMR. An exception is the structure of DNA fragments in complexes with proteins, exemplified by the operator–*trp*-repressor complex. In such cases the long-range interactions are provided by protein contacts, allowing the detection of longer range structural features, such as bends and twists of the double helix.

Details of NMR studies of oligonucleotide structures, of their complexes with a variety of drug molecules and of the methods developed for this purpose are given in several articles elsewhere in this Encyclopedia. A critical evaluation of the applicability of NMR methods to solution structure of nucleic acids, published in 1991 by Wemmer,⁴⁶ should be read by anyone concerned with the significance of published oligonucleotide structures derived from NMR data. In no other field of biological applications of NMR has the disregard for the principles and pitfalls of NMR structure determination outlined in the preceding section produced as much questionable, and outright erroneous, published information. A dramatic claim for the existence of highly

bent, twisted and otherwise distorted, nearly doughnut-shaped DNA segments had already been published in 1988.⁴⁷ A re-examination of the method of analysis used in these studies brings to light the danger of overinterpreting the precision of distance constraints by calibrations that do not take either spin diffusion or internal motions into account and using a global optimization procedure with a set of only local constraints. Structures calculated by such oversimplified procedures are not likely to be correct. The extent to which the use of NMR methods for studies of nucleic acid structures is meaningful has not changed since it was succinctly summarized by Wemmer: ‘Aspects of secondary structure and the general positioning of bases can be determined readily from NMR data. Highly quantitative structure analyses must be viewed as quite questionable at this time.’

2.3 Solution Structures of Noncovalent Complexes

The solution structure of noncovalent complexes (in particular DNA–protein and small ligand–protein complexes) can also be defined by the procedures described above. The only difference is that docking constraints (e.g. NOEs between the ligand and the protein or between two macromolecules) have to be used in addition to the usual set of constraints defining the geometry of each of the components. The docking constraints play a crucial role in defining both the topology of the complex and the structural changes that occur upon complex formation. For DNA–protein complexes, relatively few docking constraints will define the geometry and, where applicable, the symmetry of the complex, and identify the regions of contact. Many such constraints are required to define the fine structure of the interface and the structural changes resulting from complex formation. In the case of the operator–*trp*-repressor complex already mentioned as the largest NMR structure to have been determined so far, a considerable distortion of both the DNA and the protein structure occurs upon binding in the presence of tryptophan, so that simple docking of the independently determined operator and repressor structures using only experimental docking constraints gives only an approximate structure, although its symmetry is correct. A complete *de novo* structure determination was necessary in this case to account for all of the data in detail. The resulting structure is shown in Figure 11.¹⁶

Two considerations are of importance when viewing reported ligand–protein structures. First, several of the structures that are found in the literature are based on model building only—i.e. on rigid body docking of independently determined ligand and protein structures (in the case of DNA based on a standard B-DNA model).⁴⁸ Such structures must be regarded as hypothetical and must be distinguished from structures obtained by a bona fide complete structure determination, to which, as the *trp*-system example shows, they are by no means equivalent. Second, discrepancies between NMR structures and crystal structures of the same complex must be examined with care, as they may provide important information. In the case of the *trp*-repressor–operator complex, direct hydrogen bonding contacts between the DNA and the protein are compatible with all observed NMR constraints. In the crystal structures of the same complex, several protein–DNA contacts are mediated by water molecules, a rather unusual

Figure 11 Solution structure of the *trp*-repressor–ODNA complex. The view shows the repressor backbone with DNA at full atomic representation. (Reproduced from H. Zhang, D. Zhao, M. Revington, W. Lee, X. Jia, C. Arrowsmith and O. Jardetzky, *J. Mol. Biol.*, 1994, 238, 592)

feature even among protein–DNA complexes determined by X-ray diffraction. For the study of noncovalent complexes, NMR may prove to be the better method. In several reported cases it is apparent that flexible protein segments are involved in the interaction with DNA,⁴⁹ and flexible peptides are found at protein binding sites.^{50,51} The flexibility of such structures means that they are particularly vulnerable to the action of external forces, and specifically those that are responsible for crystallization. Whereas distortion of tightly packed covalent protein structures upon crystallization is generally regarded as minimal, this is not necessarily the case when the much weaker noncovalent complexes are examined. One should therefore expect to encounter artifacts resulting from crystallization which would not occur in the solution structure. Only a minor distortion of specific contacts is required to allow water molecules in the crystallized complex where they would not normally occur in solution, creating the potentially erroneous impression that they play a functional role.

3 MACROMOLECULAR DYNAMICS

NMR spectra are sensitive to molecular motions over a wide range of frequencies. The timescales on which each of the principal measurable NMR parameters—chemical shifts, line intensities, coupling constants and relaxation rate constants (including linewidths and NOEs), and proton exchange rates—provide dynamic information are summarized in Figure 12.⁵² The total range spans from picoseconds to hours, days and weeks, making NMR a uniquely useful method for the study of dynamic processes in molecules (as in the case of structure) at atomic resolution. Although other spectroscopic methods allow the study of dynamic processes at selected points in a protein structure, focusing on a single atom or a group of atoms, no other method allows the *simultaneous* observation of dynamic phenomena in different parts of the molecule at atomic resolution. Application of high resolution NMR to the study of proteins has led to the discovery of several types of dynamic phenomena in protein molecules, most of which are as yet not fully

understood. We can distinguish at least five categories of such phenomena: (1) variation of fast (i.e. nanosecond) motional frequencies along the polypeptide backbone; (2) enhanced conformational flexibility of longer backbone segments on different timescales (nanoseconds to seconds); (3) ‘breathing’ of folded protein made evident by the free rotation of aromatic amino acid side chains in the tightly packed core of many proteins or by rapid exchange of backbone NH protons with the solvent (micromillisecond); (4) conformational equilibria involving entire domains (usually on a millisecond to second timescale); and (5) dynamic states of partially folded structures observed under denaturing conditions. Variations of motional (rotational) frequencies along an amino acid side chain on the protein surface might be considered as a sixth category, but they are relatively well understood and of interest for the understanding of protein function only in the special cases when the motion becomes hindered by interactions.

3.1 Protein Dynamics

3.1.1 Fast Motional Frequencies along the Backbone

The possibility of resolving and assigning individual resonances for most atomic groups in the protein has brought with it the possibility of mapping the motional frequencies, which are reflected in relaxation parameters, for each individual group. Generally, a combination of relaxation parameters— T_1 , T_2 and $T_{1\rho}$, and for ^{13}C and ^{15}N atoms with covalently bonded protons, also the NOE—has to be used to define the motions of interest and their frequencies. A most exact analysis of the motions along the peptide backbone allows the direct calculation of individual spectral density functions for individual interatomic vectors from experimental data without recourse to any (always arbitrary) model for their analysis. This type of analysis does not directly define a physical picture of the motions—a motional model giving a correct prediction of the spectral density functions is required for this purpose. However, *variations* in motional frequencies and amplitudes along the backbone can be mapped, although it should be said that they are also evident from the raw relaxation data themselves, independently of any method of analysis. The experimental results reported so far reflect two types of situation: (a) relatively rigid proteins, e.g. the IIA domain of glucose permease,⁵³ for which the variation in the magnitude of measured relaxation parameters along the polypeptide backbone is minimal; and (b) proteins containing segments of varying flexibility, e.g. staphylococcal nuclease, eglinC, gal4, calmodulin⁵⁴ and others. Larger amplitude motions are frequently observed in loops and at hinges between compact domains. In some cases these motions may involve the entire loop, leading to a poor definition of the NMR structure, whilst in others they are limited to one or a few residues at each end of the loop, the remainder of the loop appearing well structured. In other cases large-amplitude motions affect a group of residues within a unit of secondary structure, as in the case of interleukin or staphylococcal nuclease. There is as yet no clearly recognizable pattern to the distribution of amplitudes and frequencies of these fast motions, and it is not yet clear whether they play any role in protein function or are irrelevant byproducts of protein architecture.

Figure 12 Timescales in seconds defined by NMR parameters. (I) Region of fast exchange; (II) region of intermediate exchange; (III) region of slow exchange. (Reproduced from O. Jardetzky and G. C. K. Roberts, 'NMR in Molecular Biology', Academic Press, New York, 1981)

The interpretation of the observed spectral density functions in terms of motional parameters, i.e. amplitudes and frequencies, depends of course on the construction of an appropriate model. Such models are necessarily complex and are only now beginning to emerge. The models used initially—anisotropic rigid body rotation, fast rigid rotor on a slower rigid rotor, wobbling on a cone^{55,56}—were too simplistic to account for more than a few data points. Model-free approaches, which have enjoyed some popularity, can generate detailed motional maps, but fail to provide a complete insight into their nature. The original model-free approach of King and Jardetzky⁵⁷ can account for the observed motional frequencies, but not for the detailed amplitude characteristics of the motion. The model-free approach of Lipari and Szabo⁵⁸ actually represents a very restrictive model, equivalent to rigid body rotation with one degree of internal motional freedom or a two-term expansion of the King–Jardetzky formalism. Not surprisingly, it fails to account for the more detailed motional maps now obtainable experimentally,⁵⁹ just as any other of the oversimplified models. In the experimental maps, one can frequently see regions affected by slower motions of some kind, largely reflected in anomalous values of T_2 . No fully satisfactory treatment of such slow motions has as yet been developed, although it has been suggested that they represent concerted motions, such as solitons.⁶⁰ Molecular dynamics simulations have shown promise in accounting for fast rotations in protein side chains.⁴² Their great attraction is that they allow an independent, rigorous, a priori calculation of spectral density functions, which can then be compared with those obtained from experiments. In principle, molecular dynamics can provide a complete explanation of all dynamic processes observed in proteins, including the slower (micro- to millisecond) motions. Unfortunately for the nanosecond and slower motions observed along the backbone, rigorous molecular dynamics simulations are not yet practical. A complete and correct description of the patterns of the motions observed along the polypeptide chain

remains a subject for future research, as does the evaluation of their functional significance.

3.1.2 Conformational Flexibility

Conformational flexibility of a longer contiguous segment of the peptide backbone may occur on any timescale and can be reflected in a different set of NMR parameters in different cases. Many examples of flexible segments varying in length from 7 to 25 or even more amino acid residues are now known. Some occur at the *N*- and *C*-terminals of peptide chains and some in their interior. The earliest discoveries of flexible segments—those of the RNA-binding site in Tobacco Mosaic Virus (TMV),⁶¹ the DNA-binding domain of the *lac*-repressor,⁶² histones,⁶³ and the S1 domain of myosin⁶⁴—were based on the finding of anomalously narrow lines (long T_2) reflecting free rotation on a nanosecond timescale. In the crystal structure of TMV the corresponding segment was found to be disordered. In the more recent examples—the DNA-binding domains of the *trp*-repressor⁶⁵ and antennapedia homeodomain,⁶⁶ and the B-chain of insulin analogs⁶⁷—fast motions do not play a prominent role, and the most striking finding is the absence of NOEs needed to define the structure of the segment. This finding is usually accompanied by the finding of unusually rapid exchange rates for the peptide backbone protons. Structure calculations on molecules containing such segments lead to the conclusion that the segments are disordered in solution. However, the apparent disorder may reflect averaging between two or more well-defined conformations. In the absence of line narrowing and other anomalies in the relaxation parameters, the conclusion must be drawn that the conformational averaging occurs on timescales longer than nanoseconds. In favorable cases, where the segment undergoes transitions between a closed and an open form of a secondary structure (e.g. a helix-coil transition), the rates of conformational averaging can be estimated from rates of backbone proton exchange. A very detailed study

of conformational flexibility in the DNA-binding domain of the *trp*-repressor has led to the conclusion that the interplay of dynamic processes in peptide segments can be quite complicated. It is thus necessary to distinguish between *true flexibility*, or *true disorder*, and *apparent flexibility*, or *apparent disorder*. In the case of true flexibility one will find ‘random coil’ behavior by all NMR criteria—rapid averaging of chemical shifts and coupling constants, rapid proton exchange and rapid motions reflected in narrow lines, as well as disappearance of NOEs and other cross peaks in multidimensional spectra. These are findings typical of the N- and C-terminal peptide segments in several proteins. On the other hand, in cases of apparent disorder or flexibility the findings tend to be contradictory, as they are in the case of the *trp*-repressor. The DNA binding segment appears disordered if one relies on the observations of sequential NOEs, backbone proton exchange rates and backbone ^1H T_1 measurements. At the same time, it appears ordered from the ^{15}N relaxation profile and from the finding of α -CH shifts typical of α -helical structures. The findings can be reconciled if one infers that the segments are largely helical on a nanosecond timescale, but the helices are unstable on longer (in this case millisecond) timescales, and the closed state (corresponding to the formation of a hydrogen bond) at all sites exists less than 100% of the time. One is thus dealing not with a continuum of conformational states, which defines true flexibility, but rather with a structure that is unstable and hence ‘flexible’ only on a much longer timescale. A similar phenomenon is known to occur in the ready unfolding of the *lac*-repressor DNA-binding domain. In this case sufficient NOEs were found initially to define a helical structure, but the structure was shown to be unstable under a variety of ambient conditions.⁶⁸

The quantitative analysis of the apparent disorder cases requires a wide range of NMR measurements and can be rather complicated. Selective attention to only some of the NMR parameters (e.g. only the set of observable NOEs, which has become common practice in NMR structure determination) will confuse true and apparent disorder and lead to erroneous conclusions, as will the uncritical application of commonly used theoretical treatments [e.g., those for backbone proton exchange, which are based on simplified assumptions of relatively stable secondary structures (see *Hydrogen Exchange and Macromolecular Dynamics*), and do not apply in the general case]. The paradigm for the analysis of the general case was first worked out for the *trp*-repressor and is briefly summarized here because of its wide applicability. The picture of the repressor helix–turn–helix DNA-binding domain that has emerged from this analysis is as follows: the region consists of two helices which retain their overall helical shape at all times, but with hydrogen bonds opening, one at a time, on a millisecond time scale.

Three types of experiment are necessary to calculate the exchange rates (or lifetimes) between the different states in this type of situation. First, the classical hydrogen–deuterium exchange experiments can identify hydrogen bonds that are stable on timescales from minutes to years. Second, proton T_1 relaxation, with and without solvent presaturation, will identify those hydrogen bonds undergoing an exchange on a millisecond to second timescale. Third, the pH dependence of the T_1 will allow calculation of opening and closing rates, since the intrinsic exchange rate is known to be pH dependent and can be independently evaluated from the amino

Figure 13 The generalized Linderstrøm–Lang model

acid sequence (see *Hydrogen Exchange and Macromolecular Dynamics*).

The simplest model that can account for the observation is the generalized Linderstrøm–Lang model, which is free of all of the usual assumptions about the relative magnitudes of helix opening, helix closing and intrinsic exchange rates^{69,70} (Figure 13). The magnetization transfer equations describing this model without arbitrary simplification are the generalized McConnell equations:

$$\left. \begin{aligned} \frac{dM_A}{dt} &= -R_{1A}(M_A - M_A^{\text{EQ}}) - k_{\text{open}}M_A + k_{\text{close}}M_B \\ \frac{dM_B}{dt} &= -R_{1B}(M_B - M_B^{\text{EQ}}) + k_{\text{open}}M_A - k_{\text{close}}M_B \\ &\quad - k_{\text{intr}}M_B + k'_{\text{intr}}M_{\text{H}_2\text{O}} \\ \frac{dM_{\text{H}_2\text{O}}}{dt} &= -R_{1\text{H}_2\text{O}}(M_{\text{H}_2\text{O}} - M_{\text{H}_2\text{O}}^{\text{EQ}}) - k'_{\text{intr}}M_{\text{H}_2\text{O}} + k_{\text{intr}}M_B \end{aligned} \right\} \quad (15)$$

whose solution is:

$$\begin{aligned} M_A &= C_1 e^{\lambda_1 t} + C_2 e^{\lambda_2 t} + C_3 \\ M_B &= D_1 e^{\lambda_1 t} + D_2 e^{\lambda_2 t} + D_3 \end{aligned} \quad (16)$$

The symbols are defined in the Appendix at the end of this article.

The solution of these equations predicts pH independent single exponential behavior for the NHs of slowly exchanging (stable) hydrogen bonds, and pH dependent double exponential behavior for hydrogen bonds exchanging on a timescale comparable to the intrinsic relaxation rate, T_1 (milliseconds to seconds).^{71,72}

In the study of the pH dependence of relaxation in the *trp*-repressor, the observation was made that, even though the data could be accounted for by this model, the conclusions drawn about the percentage helicity and opening and closing of helices were contradicted by other experimental findings. The contradictions are summarized in Table 2.

To account for all the data simultaneously, one either has to assume that the ‘open’ state in the Linderstrøm–Lang model is not completely open, characterized by $k_{\text{intrinsic}}$ slower than the rate observed in a free peptide, or alternatively, invoke a three-state model allowing for the observed slow exchange between

Table 2 Contradictory Evidence on the Percentage Helicity and Opening and Closing of Helices

Helix–Coil Transition	Process Monitored by T_1
$\geq 90\%$ helicity (δ , ^{15}N)	20–40% ‘helicity’
$k_{\text{ex}} > 100$ Hz ($\Delta\delta$, temperature dependent)	$0.4 < k_{\text{ex}} < 4$ Hz

Figure 14 The three-state model

'locked' and 'unlocked' states of the DNA-binding helices, and a rapid helix–coil equilibrium (Figure 14). The equations for this model, too complex to be reproduced here, reduce to the form of equations (15) and (16) if the helix–coil equilibrium is rapid. The physical meaning of the observed rates is, however, in either case different than that originally envisioned. This underscores the importance of comparing different types of NMR and other data if one is to arrive at a correct description of solution structures and their dynamics.

The functional significance of segmental flexibility—either true or apparent—may well be to facilitate conformational adjustments on binding to ligands. It is probably no accident that segmental flexibility appears prevalent in the binding domains of DNA (and RNA) binding proteins. Especially in the case of repressors, such as the *trp*-repressor, which are known to interact with more than one DNA sequence, such conformational flexibility could be necessary to make the optimal contacts in each case, using the same amino acid sequence and the same secondary structure. Similarly, in the case of insulin, flexibility of residues 20–30 in the B chain could facilitate conformational adjustments upon receptor binding. A very interesting example of flexibility associated with the ability of a segment to assume a helical conformation in the crystal and a β -turn conformation in solution has been described for chicken egg-white cystatin.⁷³ The function of this segment is as yet unknown, and much remains to be learned about protein function from the NMR study of similar phenomena in other proteins.

3.1.3 'Breathing' Motions

Breathing motions first became apparent in the spectra of selectively deuterated staphylococcal nuclease, which showed that the tyrosines in the interior of the molecule had motionally averaged spectral lines.⁷⁴ This phenomenon was extensively studied on several proteins in the 1970s, and the rates for the 180° flip were estimated to lie between 102 and 104 s⁻¹. A temperature dependent transition from the 'frozen' configuration at low temperatures to the freely rotating state at room temperature was described for ferrocycytochrome C.⁷⁵ In the case of parvalbumin, low amplitude librations of phenylalanine rings in the core on a nanosecond timescale, detectable by ¹³C relaxation, could be shown to precede the relatively rare 180° flips on a microsecond timescale, evident from chemical shift averaging.⁷⁶ Rotation of rings in the interior of the protein has been and always needs to be considered in the interpretation of NOEs used for a protein structure determination.¹⁸ The

relationships of such 'breathing' motions to backbone motions and segmental flexibility have not yet been sufficiently studied, but it may be expected that they will emerge from comparisons of the relative timescales, directions, and amplitudes. Ideally, the relationship should be given by molecular dynamics calculations, but molecular dynamics simulations on the required micromillisecond timescales are impractical at present.

3.1.4 Conformational Transitions

Conformational transitions usually manifest themselves as changes of local structure. The ease of detecting and describing them depends on the lifetimes of the conformational states involved. If the exchange between the states is slow on the chemical shift timescale, i.e. the lifetimes of the states are long compared to the inverse of the chemical shift difference between the peaks representing the two states, the states can be observed and described separately by standard structure determination methods. Into this category fall the conformational readjustments occurring in Ca²⁺ binding proteins upon addition of Ca²⁺, which have been studied extensively and are described elsewhere in this Encyclopedia, and many others. If the exchange rate is of the same order as the frequency difference of chemical shifts between the two states, the transition is often observable as a selective line broadening. The early NMR detection of conformational equilibria, even in simple enzymes such as pancreatic ribonuclease A,⁷⁷ was based on this phenomenon. As the exchange rate becomes more rapid on the chemical shift timescale, the individual conformational states can no longer be resolved. In the intermediate exchange range it is possible to infer from the data that an exchange process is occurring, but not the nature of the conformers or their number. In the rapid exchange case, even the existence of the exchange process itself is not directly detectable. This leads to the well-known problem that a structure determination on a system undergoing rapid averaging between two or more distinct conformations leads to a structure that has no physical meaning.^{52,78} Attempts to resolve this dilemma by modeling the individual conformers and calculating the pattern of NMR parameters that would correspond to a dynamic average of the multiple states have been published.⁷⁹ A residual of uncertainty as to the adequacy of the dynamic model invoked will always remain for structures determined on systems undergoing conformational averaging. In formulating and testing such a dynamic model, it is therefore advisable to invoke a wide range of NMR experiments and test the interpretation of results for internal consistency.

3.1.5 Dynamic States of Partially Folded Structures and the Problem of Protein Folding

These topics are an active area of current research, and NMR approaches to this problem are discussed in detail elsewhere in this Encyclopedia. Suffice it to say here that studies of this type—conducted on objects known to be unstable—are especially vulnerable to the problems of conformational averaging discussed above. At the same time, it must be pointed out that even NMR 'structures' of intermediates which have no physical existence ('apparent structures') may be useful as indicators of the trends of changes occurring in

the structure as it folds or unfolds, respectively, and thus point to the deciphering of the folding pathway. An interesting recent example has been provided by the work of Dobson and coworkers⁸⁰ on the folding pathway for the assembly of hen egg-white lysozyme. The pathway appears to proceed from: (1) the formation of α -helices; to (2) the formation of two-helix bundles; to (3) the addition of a β -structure to form a 'molten globule' that topologically resembles the final structure, but is not well defined in detailed contacts and must undergo a rearrangement to yield, (4) the fully folded lysozyme.⁷³ A caveat emerging from this study is that alternative pathways are also compatible with all of the available NMR data. This reflects the ambiguity of the NMR data, but may also reflect the actual existence of multiple folding pathways. In a case of this kind, extensive correlation of the NMR findings with findings obtained by other physical methods is essential for the resolution of ambiguities.

3.1.6 Implications of Internal Motions and Flexibility for Structure Determination by NMR

The most serious problem to be considered when deriving solution structures of proteins from NMR data is that of conformational averaging, as discussed above. The problem is ubiquitous, and the burden of proof that the reported structure is rigid as calculated, remains on the investigator. For small compact globular proteins the problem is minimal. Averaging in a single potential well around a single set of coordinates is, for all practical purposes, indistinguishable from the case of a rigid structure, and corrections for this type of averaging have been proposed.⁴² Short disordered regions are easily detected by the absence of NOEs, as in the case of insulin. The problem is much more serious for larger proteins, where averaging between ordered local structures may occur, as in the case of the *trp*-repressor. In such cases a detailed study of the dynamics becomes necessary, before the proposed structure can be given full credence. As has been pointed out already, many years ago,^{23,78} to derive correctly a protein solution structure from NMR data, it is necessary to understand the dynamics of the protein in detail, and vice versa. Simple NMR structure determination is limited to simple objects. For most proteins, the study of structure and dynamics must, of necessity, go hand in hand.

3.2 Nucleic Acid Dynamics

Two types of rapid motion are known to occur in nucleic acid structures: (1) puckering of the phosphate backbone, reflected in the rapid averaging of ³¹P chemical shifts so that typically, with few exceptions, only a single phosphate NMR signal is observed in both short oligonucleotide double helices and long (300–600 base pair) stretches of DNA; and (2) puckering of the sugar rings (deoxyribose in DNA and ribose in RNA, respectively), usually described as an exchange between a 2'-*endo* and a 3'-*endo* conformation.⁸¹ Since the exchange rate is rapid on both the chemical shift and the coupling constant timescales (so that only time-averaged parameters are observed and individual states can not be resolved), it remains possible, but unprovable, that the exchange involves more than two states. Both of these motions clearly reflect thermal fluctuations. If they have any

functional significance, it is to reflect the inherent flexibility of nucleic acid strands, necessary for the unwinding of double-stranded structures in the processes of replication, transcription and translation. It has been proposed that these motions may be accompanied by changes in helical twist.⁸² On the other hand, wobbling of bases in double-stranded structures is rarely of sufficient amplitude to be reflected in NMR parameters, except at the fraying ends of oligonucleotide sequences.⁸³ Motions within the DNA double strand can be modulated and damped by the binding of intercalating agents. For purposes of structure calculations, short double-helical oligonucleotide strands can be treated as if they were rigid, since all of the described motions result only in averaging about a single energy minimum, i.e. within a single potential well. As yet, insufficient NMR data on the structure and dynamics of RNA are available to judge whether the more complex RNA structures found in crystallographic studies also undergo more complex and functionally significant motions. The existence of such motions can for the present only be inferred from the diversity of binding and catalytic interactions within the RNA family, observed in biological experiments. Conformational flexibility is a prerequisite for such diversity. Specific examples of nucleic acid dynamics are discussed elsewhere in this Encyclopedia (see *Nucleic Acids: Spectra, Structures, and Dynamics*).

4 MOLECULAR INTERACTIONS

Molecular interactions of small ligands with macromolecules were among the first biological problems to be successfully studied by NMR. As early as 1961 a relaxation method for the determination of the groups involved in ligand–protein interactions had been developed in the author's laboratory.^{84,85} With the methods then available, it was possible to infer which part of the flexible ligand—e.g. the phenyl ring of penicillin, rather than the penicillanic acid moiety—was bound to the protein. Interesting observations on different modes of binding in the sulfonamide family could be made, distinguishing binding by the sulfonamide ring from binding of an aromatic substituent to the same protein.⁸⁶ Later, it became possible to infer structures of inhibitor binding sites from a combination of NMR observations of ligand and protein side chains, as in the cases of pancreatic ribonuclease⁸⁷ and staphylococcal nuclease.⁸⁸ The binding of a transition state analog to lysozyme was also the subject of one of the early studies.⁸⁹ With modern technology it is possible to obtain detailed structures of binding sites, even for proteins that are for the time being too large to be amenable to a complete structure determination. A classic example is the detailed study of the binding of substrates and cofactors to dihydrofolate reductase, carried out by Roberts and coworkers.⁹⁰ In these studies it was found, long before a complete structure determination, that the cofactors NAD and NADH bound in different orientations, and, in a corresponding study of the dynamics, that the bound heterocyclic rings were able to undergo 180° flips in the bound state. A similar detailed study of the anti-TEMPO hapten antibody Fab fragment binding site by McConnell and coworkers⁹¹ revealed that hapten binding caused a conformational change involving the displacement of a tyrosine side chain near the binding site to accommodate the hapten moiety. A detailed NMR structure of the Fab

fragment is not yet available. A complete structure of the tryptophan binding site in the *trp*-repressor was obtained in the course of the structure determination. It must be said, however, that the precision with which noncovalent structures can be defined from NMR data still leaves something to be desired, although the general configuration of the complex can be clearly outlined and the possibilities of forming different contacts evaluated. In dynamic NMR studies of ligand-protein interactions, the lifetimes of the bound and free states and the binding constants can be estimated. For typical small molecule ligands, the dwelling time on a protein falls in the millisecond range.

NMR studies of binding sites are particularly attractive when a comparison of the binding modes of different ligands (e.g., in a series of analogs) are needed, because of the relative speed and efficiency with which comparisons can be made. For ligands binding in a similar manner, the spectral changes (e.g., in the observed NOE pattern) from one compound to the next will be minor, and similarity of binding can be inferred from the similarity of the spectra without a complete reanalysis of the spectra in each case. Only when the binding patterns are different will the spectral changes be marked and require a de novo interpretation. A further advantage of NMR studies in this context is that comparative kinetic information on the exchange rates between the bound and free states is readily obtainable.

5 PROTEIN FUNCTION

Studies of protein function made possible by NMR fall into several categories. Very few detailed studies of this kind have as yet been carried out, but the possibilities have been clearly recognized.

The function of enzymes can be studied at several levels. Rates of enzymatic catalysis can be followed by observing the disappearance of substrates and appearance of products in (real) time. Structures of enzyme-inhibitor, enzyme-substrate or enzyme-transition-state analog complexes can be determined and examined for clues concerning the involvement of different groups at the binding site in the process. The first successful example of such a study was that of pancreatic ribonuclease A,^{77,87} leading to a proposed mechanism that has since been confirmed by several kinetic and structural methods. Conformational changes and conformational equilibria involved in allosteric regulation can be defined, as described above. The obvious advantage of NMR over X-ray diffraction in this context is that the enzyme can be studied in its natural environment in solution, and that the dynamic processes involved can in many cases (though not always) be observed directly rather than being inferred from the initial and final states that can be crystallized.

The function of regulatory proteins, in which points of contact between the protein and DNA can be altered by a small molecule ligand, can be examined in much the same way as the function of allosteric enzymes. The study of the operator-*trp*-repressor complex, which forms in the presence of tryptophan and dissociates in its absence, can serve as the prototype for all studies of this type. This system is not only, as already noted, the largest molecular entity determined by NMR, but also the only complete allosteric regulatory complex analyzed by NMR methods in detail. All other NMR studies of protein-DNA interactions that have been reported involve binary complexes between the two macromolecules, with the regulatory function and ligand binding sites having been lost in the preparation of DNA-binding domains small enough to be easily studied by NMR. Structural studies of the complete system, including the ternary ligand-protein-DNA complex revealed a first conformational change on corepressor tryptophan binding and a further conformational change on the formation of the ternary complex with operator DNA. Dynamic studies revealed a stabilization of the DNA binding region by the binding of tryptophan and a further stabilization upon the formation of the ternary complex. The actual process is therefore more complex than the simple model commonly used for regulatory proteins—a single ligand induced conformational transition which aligns the DNA binding sites for better docking. It is to be expected that further, as yet unanticipated, variants of regulation by structural change will be uncovered in the course of studies on other systems.

Proteins involved in signal transduction and information transfer are also thought to function by undergoing structural transitions and, therefore, can be studied by the same techniques as those applied to the *trp*-repressor system, as can transport proteins functioning by an allosteric mechanism.

6 CONCLUSIONS

In summary, it can be said that the biological-NMR literature to date has laid all the necessary foundations for the study of protein structure, dynamics, interactions and function, devising and testing the required techniques and prototype experimental protocols on selected prototype systems. To a lesser extent, this can also be said of nucleic acids. Some technical development still remains to be done, in particular testing combinations of techniques to solve specific problems. The full range of potential applications remains in the future.

7 APPENDIX: DEFINITION OF SYMBOLS USED IN EQUATION (16)

$$\lambda_1 = \frac{-\frac{1}{T_{1A}} - k_{\text{open}} - \frac{1}{T_{1B}} - k_{\text{close}} - k_{\text{intrinsic}} + \sqrt{\left(\frac{1}{T_{1A}} + k_{\text{open}} - \frac{1}{T_{1B}} - k_{\text{close}} - k_{\text{intrinsic}}\right)^2 + 4k_{\text{close}}k_{\text{open}}}}{2}$$

$$\lambda_2 = \frac{-\frac{1}{T_{1A}} - k_{\text{open}} - \frac{1}{T_{1B}} - k_{\text{close}} - k_{\text{intrinsic}} - \sqrt{\left(\frac{1}{T_{1A}} + k_{\text{open}} - \frac{1}{T_{1B}} - k_{\text{close}} - k_{\text{intrinsic}}\right)^2 + 4k_{\text{close}}k_{\text{open}}}}{2}$$

$$\begin{aligned}
C_1 &= \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) \left\{ \frac{(M_A^i - C_3) \left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) - k_{\text{close}}(M_B^i - D_3)}{\left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}} \right\} \\
C_2 &= k_{\text{open}} \left\{ \frac{(M_B^i - D_3) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}(M_A^i - C_3)}{\left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}} \right\} \\
D_1 &= k_{\text{close}} \left\{ \frac{(M_A^i - C_3) \left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) - k_{\text{close}}(M_B^i - D_3)}{\left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}} \right\} \\
D_2 &= \left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) \left\{ \frac{(M_B^i - D_3) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}(M_A^i - C_3)}{\left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}} \right\} \\
C_3 &= M_A^{\text{EQ}} + \frac{f k_{\text{close}}}{\left(\frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}} \\
D_3 &= M_B^{\text{EQ}} + \frac{f \left(\frac{1}{T_{1A}} + k_{\text{open}} \right)}{\left(\frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}}
\end{aligned}$$

For presaturation experiments: $f = -k_{\text{intrinsic}}M_B^{\text{EQ}}$. For no-presaturation experiments: $f = 0$.

1 INTRODUCTION

Atomic resolution structure determination of biological macromolecules dates back to the 1950s, when the first amino acid sequence determination was achieved with insulin¹ and the first 3D protein structures were obtained by X-ray diffraction in single crystals of myoglobin² and hemoglobin.³ Nearly three decades later, in 1984, the first NMR structure determination of a globular protein in solution was completed (Figure 1),⁴ using a strategy that was described explicitly 2 years earlier.^{5,6} Structure determination by NMR is thus a recent addition to the arsenal of experimental techniques available in structural biology. However, compared with the slow growth of protein crystallography in the 1960s, where only one additional structure determination was completed within 8 years after the initial success with myoglobin and hemoglobin, there were numerous practical applications of the NMR structure determination method for proteins and nucleic acids soon after 1985. During the 3 year period 1990–1992, 121 new NMR structures were published^{7–9} (for comparison, 405 new X-ray crystal structures were published during the same period^{7–9}), and the pace is still accelerating. As a result, the field has evolved rapidly, and in addition to academic institutions the modern biotechnology industry has become heavily involved in biomolecular NMR structure determination.

The introduction of NMR as a second method for macromolecular structure determination is of fundamental interest because NMR can provide data that are in many ways complementary to those obtained from X-ray crystallography. Combined use of the two techniques thus promises, in particular, to widen our view of protein molecules for a better grasp of the relationships between structure and function, and thus to provide a more refined platform for rational, structure-based drug design, and more generally engineering of proteins with

Figure 1 Stereo view of the three-dimensional NMR solution structure of the protein bull seminal proteinase inhibitor IIA (BUI IIA), determined in 1984. All bonds connecting heavy atoms are shown for the entire polypeptide chain of 57 residues. (The drawing was prepared using the atom coordinates from Williamson et al.⁴)

improved or entirely novel functions. These intimate links between structural biology and protein biotechnology have greatly influenced the rapid evolution of NMR structure determination.

The complementarity of the structural information obtained from diffraction techniques or from NMR results from the fact that the timescales of the two types of measurements are widely different^{10,11} and that, in contrast to the need for single crystals in diffraction studies, the NMR measurements use proteins or nucleic acids in solution or in other noncrystalline states. The most obvious consequence is that NMR can be applied to proteins for which no single crystals are available, thus yielding new structures that cannot be solved by any other method. Conversely, the solution NMR method has so far been applied successfully only to relatively small proteins or nucleic acid fragments with molecular weights up to about 20 000. In the future this size limit may possibly be increased twofold, but X-ray diffraction will foreseeably remain the method of choice for the determination of large structures (perhaps supplemented by solid state NMR in the not too distant future). To provide a balanced view of the potentialities of solution NMR it should be added that present biochemical technology can open ways for NMR investigations of larger systems. For example, individual, biologically functional domains excised by enzymatic or chemical cleavage from large proteins, or expressed separately as recombinant proteins, may be accessible for NMR structure determination. Or, in a more general vein, conclusions from systematic comparisons of small proteins in crystals and in solution may be projected to larger molecules for which only a crystal structure is available. Comparisons of corresponding structures in single crystals and in noncrystalline states are therefore highly relevant, all the more since the solution conditions for NMR studies can often be chosen so as to coincide closely with the natural, physiological environment of the protein.¹⁰

Having staked out potentialities and areas of applications for macromolecular NMR structure determination in solution, the remainder of this article is focused on 'how to do it'. As numerous other contributions in this Encyclopedia relate to this theme, the attempted goal is to provide a framework that can accommodate the different, presently used technical approaches. Also, for simplicity of the presentation the discussion will be mainly focused on proteins, with some reference to work with deoxyribonucleic acids (DNA) and ribonucleic acids (RNA).

2 SURVEY OF THE METHOD

Figure 2 presents an outline of the course of an NMR structure determination.¹⁰ Individual steps are the sample preparation, the NMR measurements, the crucial problem of obtaining assignments of the NMR lines to individual atoms in the polymer chain, and the collection and structural interpretation of NMR conformational constraints. These individual steps will be further discussed in the following sections.

In present practice^{10,12} the sequence of steps taken during a structure determination corresponds largely to the flow diagram of Figure 2. Thereby, as is indicated by the arrows in Figure 2, one goes through repeated cycles of collection of conformational constraints and structure calculation, and even some sequence-specific resonance assignments may be reassessed during the structure calculation. In principle, however, the entire spectral analysis from peak picking to resonance assignments to the final structure determination is largely self-contained, and might conceivably at some future stage be handled as a single, computer-supported process.

It is a special feature of protein structure determination by NMR that the secondary polypeptide structure, including the connections between individual segments of regular secondary structure, may be known early on from the data used for obtaining the resonance assignments, actually before the structure calculation is even started.^{13–15} This contrasts with the situation in X-ray crystallography, where regular secondary structures are usually identified only at later stages of a project, and it opens interesting possibilities for the support of X-ray crystal structure determinations on the basis of solution NMR data.¹⁶

Figure 2 Diagram outlining the course of a macromolecular structure determination by NMR in solution (see text)

3 SAMPLE PREPARATION FOR NMR STRUCTURE DETERMINATIONS

Let us assume that we start work with a highly purified, homogeneous preparation of the molecule to be studied. For proteins, such samples may either be isolated from natural sources, obtained by recombinant techniques or, for smaller polypeptides, prepared by chemical synthesis. For nucleic acids, complete structure determinations have so far been achieved only with synthetic fragments. The compound is dissolved in 0.5 mL of water, and the ionic strength, pH, and temperature may be adjusted so as to ensure near-physiological conditions (for proteins it is advantageous to work in the slightly acidic pH range from 3 to 5¹⁰). The concentration should be about 1 mM, ideally 2–5 mM, so that, for example, 5–25 mg of a protein with a molecular weight of 10 000 should be available for a structure determination. Although this concentration is high relative to that of most proteins in their physiological milieu, it is not far from the total protein concentration in typical body fluids. For molecular sizes above approximately 10 000, quite often also for smaller sizes, the NMR study will have to include the preparation of compounds enriched with ¹⁵N and/or ¹³C. Uniformly isotope-labeled recombinant proteins are obtained with commonly available techniques; nonetheless, preparation of a suitable protein sample is often the bottleneck in a project. For RNA, labeling techniques have been introduced only recently, and they are still used only by a few groups. For DNA, labeling techniques are still in the process of being worked out.

Clearly, being able to work with solutions is a great asset of the NMR method. Not only can we work in near-physiological milieus, but we also get around the preparation of suitable crystals, which has been a bottleneck for so many promising X-ray structural studies. However, working with solutions also has its inherent potential difficulties. Most of all, many biological macromolecules tend to self-aggregate at the concentrations needed for NMR spectroscopy, which has slowed down many projects in our laboratory; sometimes in such situations, biochemical studies can lead to a protein analog with suitable solution behavior. Furthermore, practical difficulties may arise with the combined analysis of successive experiments, because it is nontrivial to achieve identical solution conditions in different NMR samples of the same compound.

4 NMR SPECTROSCOPY WITH BIOLOGICAL MACROMOLECULES

Two basic notions govern the selection of spectroscopic techniques used for macromolecular structure determinations. Firstly, the information needed for 3D structure determination comes almost entirely from ¹H–¹H NOEs,^{5,10} with other experimentally accessible parameters serving primarily to support rapid convergence of the structure calculations and, mostly in molecular regions with a scarcity of NOE distance constraints, contributing to the refinement of the final structure. Secondly, a twofold spectral resolution problem needs to be solved: hundreds or even thousands of resonance lines in the ¹H NMR spectrum of a biological macromolecule must be observed as separate peaks, and selective

Figure 3 Protein structure determination and ^1H - ^1H NOEs. The region ($\omega_1 = \omega_2 = 7.2\text{--}9.4\text{ ppm}$) of a 2D [^1H , ^1H]-NOESY spectrum of the *Antennapedia* homeodomain is shown, together with a line representing a polypeptide chain, where the N- and C-terminal chain ends are identified. Two proton positions are identified by circles, and straight arrows connect the corresponding diagonal peaks in the NOESY spectrum with these protons. The presence of the NOESY cross peak that correlates the two assigned diagonal peaks shows that these two protons are separated by a distance of less than about 0.4 nm, and therefore the observation of this NOE imposes a circular structure on the polypeptide chain

correlations between pairs of spins (or groups of equivalent spins) need to be established in crowded spectral regions where, for example, selective irradiation of individual resonance lines in 1D experiments would be a major technical challenge. Although the foundations of the NMR structure determination method were laid and initial polypeptide structure determinations obtained using 1D NMR experiments⁶ (see also **Wüthrich, Kurt: NMR Structures of Biological Macromolecules**), these demands are in practice met by multidimensional NMR.

As an illustration of the spectroscopic work to be done, Figure 3 visualizes part of the scheme of Figure 2 for the case of a protein structure determination. In a [^1H , ^1H]-NOESY spectrum each cross peak establishes a correlation between two diagonal peaks, as indicated in Figure 3 by a horizontal and a vertical line, and tells us that the protons corresponding to the two correlated diagonal peaks are separated only by a short distance, say less than 0.4 nm. This information is used in the following way. First, sequence-specific resonance assignments must be obtained, i.e. for all protons in the polypeptide chain the corresponding diagonal peak positions must be identified.

This is indicated in Figure 3 by the straight arrows linking two proton positions in the polypeptide with their diagonal peaks in the NOESY spectrum. With the availability of the resonance assignments, each NOESY cross peak now shows that two protons in known locations along the polypeptide chain are separated by a short distance in the 3D protein structure. Since the overall length of an extended polypeptide chain with 100 amino acid residues is about 35 nm, the NOEs may impose stringent constraints on the polypeptide conformation. In Figure 3 this is schematically indicated by the formation of a circular structure. Typically, the NOESY spectra of proteins contain hundreds of cross peaks, indicating that the 3D fold of the polypeptide chain involves a large number of circular structures of the type shown in Figure 3. With increasing size of the molecule studied and concomitant increase of the number of NMR peaks, it becomes more and more difficult to resolve and assign individual resonances in homonuclear 2D NMR spectra. In heteronuclear 3D or 4D spectra recorded with recombinant proteins that are uniformly labeled with ^{15}N and/or ^{13}C , the peaks are spread out in a third and possibly fourth dimension along the ^{15}N and ^{13}C chemical shift axes.¹⁷ For example, in the 3D ^{15}N -correlated [^1H , ^1H]-NOESY spectrum of Figure 4 the NMR peaks have been further spread out along a third frequency axis, which corresponds to the NMR frequencies of the ^{15}N spins in the ^{15}N -labeled protein. As a result, the same number of NMR peaks as would be observed in a 2D [^1H , ^1H]-NOESY spectrum (see Figure 3) are distributed among multiple ^1H - ^1H planes, typically 64 or 128. The ensuing further improved separation of the peaks in the individual planes is indispensable for work with larger proteins. To a more limited extent, improved peak separation for unlabeled proteins from natural sources can be obtained with homonuclear 3D ^1H NMR experiments.^{18,19}

5 RESONANCE ASSIGNMENTS

Proteins contain multiple units of chemically identical amino acid residues, and nucleic acids contain multiple identical nucleotides in different sequence positions. Although different types of amino acids or nucleotides can be distinguished from their NMR spin systems, multiple copies of the same monomeric unit in different sequence locations have identical spin systems. Therefore, obtaining sequence-specific assignments for biopolymers is intrinsically nontrivial. For proteins the problem was solved with the sequential assignment strategy:^{13,20,21} segments of two or several sequentially adjoining amino acid residues are identified by NMR experiments, and by comparison with the chemically determined amino acid sequence attributed to unique positions in the polypeptide chain. Two fundamentally different approaches for obtaining sequential assignments are outlined in Figure 5 and Figure 6, and are briefly explained in the following discussion.

Assignments using sequential NOEs (Figure 5) can be obtained for proteins with natural isotope distribution. The ^1H - ^1H connectivities which identify the different amino acid types are established via scalar spin-spin couplings, using COSY, TOCSY, and multiple quantum spectroscopy. Relations between protons in sequentially neighboring amino acid residues i and $i + 1$ are established by NOEs manifesting close approach between $\alpha\text{-CH}_i$ and NH_{i+1} ($d_{\alpha\text{N}}$), NH_i and NH_{i+1} (d_{NN}), and $\beta\text{-CH}_i$ and NH_{i+1} ($d_{\beta\text{N}}$). For Xxx-Pro,

Figure 4 3D ^{15}N -correlated ^1H - ^1H -NOESY spectrum of the N-terminal domain comprising residues 1–76 of the protein P22 c2 repressor. The protein was uniformly labeled with ^{15}N to the extent of 95%. (Reproduced by permission from K. Wüthrich, *J. Biol. Chem.*, 1990, **265**, 22059)

corresponding connectivities are observed to $\delta\text{-CH}_2$ of Pro in the place of the amide proton. In Figure 5, for example, observation of a NOESY cross peak corresponding to $d_{\alpha\delta}$ tells us that the protein studied contains the dipeptide segment Val-Pro. This dipeptide is then matched against the independently known amino acid sequence. If the latter contains Val-Pro only once, the assignment problem is solved. Otherwise, to distinguish between multiple Val-Pro sites, tri- or tetrapeptide segments including Val-Pro must be identified by NMR and matched against the amino acid sequence. Since in globular proteins with up to about 200 amino acid residues the probability is small that identical tri- or tetrapeptide segments occur more than once, the procedure is in principle generally applicable,¹⁰ and for small proteins it can rely entirely on homonuclear ^1H NMR experiments. Limitations arise when a substantial proportion of the H- α and amide proton chemical

Figure 5 Segment of a polypeptide chain with arrows indicating the sequential NOE connectivities with amino acids, $d_{\alpha\text{N}}$, d_{NN} , and $d_{\beta\text{N}}$, and with *trans*-proline, $d_{\alpha\delta}$ ($d_{\text{N}\delta}$ and $d_{\beta\delta}$ not shown). Stippled lines outline the individual amino acid ^1H spin systems, which can be identified via homonuclear ^1H - ^1H scalar couplings. (Reproduced by permission of Walter de Gruyter from K. Wüthrich, P. Güntert, and K. D. Berndt, in 'Innovations in Proteases and their Inhibitors', ed. F. X. Avilés, Walter de Gruyter, Berlin, 1993)

shifts are degenerate. Improved peak separation can then be obtained with homonuclear 3D NMR,^{18,19} or with 3D or 4D heteronuclear-resolved ^1H - ^1H -NOESY using uniformly isotope-labeled protein (see Figure 4).

Sequential assignments can alternatively be obtained entirely via heteronuclear scalar couplings (Figure 6). Although this approach had already been applied in 1979 by the group of the late Vladimir Bystrov, who thus obtained assignments for the polypeptide hormone apamin using the unlabeled peptide and multiple irradiation 1D NMR,²² it became a practical technique only a decade later with the availability of recombinant isotope-labeled proteins. Today, an impressive array of 3D and 4D triple resonance NMR experiments are available for the identification of intraresidual and sequential multiatom fragments in uniformly ^{13}C , ^{15}N doubly labeled polypeptide chains (Figure 6),¹⁷ which can provide the desired sequential assignments.

A general recipe on what to use in different projects is difficult to provide. Sequential NOEs studied with homonuclear ^1H NMR provide an efficient approach for most proteins with up to about 80 residues, and proteins with up to 130 residues ($M_r \sim 15\,000$) have thus been assigned. Using the additional spectral resolution obtained with uniform ^{15}N labeling (see Figure 4), assignments based on sequential NOEs have been achieved for proteins with 150–200 residues. The largest proteins assigned using ^{13}C , ^{15}N double labeling and

Figure 6 Segment of a polypeptide chain with indication of the scalar spin-spin couplings that provide the basis for obtaining sequential assignments by triple-resonance experiments with uniformly ^{13}C , ^{15}N doubly labeled proteins. The arrows and numbers indicate typical values, in hertz, of one-bond and multiple-bond heteronuclear coupling constants $J(^{13}\text{C}, ^1\text{H})$, $J(^{15}\text{N}, ^1\text{H})$, $J(^{13}\text{C}, ^{13}\text{C})$, and $J(^{15}\text{N}, ^{13}\text{C})$

triple-resonance experiments to correlate groups of atoms via the spin–spin couplings of (Figure 6) are in the range 250–300 residues. Two limiting situations are that sequential NOEs (see Figure 5) are at present the only practical way for studies of unlabeled proteins from natural sources, and that double labeling is a must for work with proteins of $M_r = 20\,000$. Otherwise, the selection of the approach may be largely influenced by the expertise and instrumentation available in the laboratory pursuing the investigation. As a rule of thumb: in any given situation, restraint in the use of isotope labeling goes along with less extensive requirements for instrument time and more exacting demands on highly qualified scientists involved in the spectral analysis. It must also be added that obtaining sequence-specific assignments for the entire polypeptide backbone does not necessarily mean that a satisfactory level of side-chain assignments can be achieved with the same approach. As was pointed out early on by the groups of Matsune Kainosho and John Markley,²³ uniform ^{13}C labeling may be indispensable for obtaining complete side-chain assignments even in relatively small proteins. Finally, it should be added that isotope labeling offers additional possibilities beyond support of a structure determination, such as relaxation studies relating to molecular dynamics, which may also play a role in making decisions on the strategy to be followed with a given system.

For nucleic acids, assignment procedures were largely patterned after those used for proteins. In contrast to the situation with polypeptide chains, assignments using intranucleotide, sequential and interstrand ^1H – ^1H NOEs are necessarily based on the assumption of a particular conformation type for the compound studied.¹⁰ For B-type DNA this approach, which was implemented primarily by the groups of Robert Kaptein, David Kearns, and Brian Reid, is highly efficient for duplexes with up to about 20 base pairs. A conformation-independent approach is also available, which uses heteronuclear scalar ^1H – ^{31}P couplings to establish sequential assignments.²⁴ In unlabeled compounds these assignments cannot readily be extended to include the resonances of the bases, which limits their usefulness.¹⁰ With suitably ^{15}N - and ^{13}C -labeled compounds, base–backbone connections can be established via heteronuclear scalar couplings, which may in the future enable complete assignments for oligonucleotide segments with non-regular conformations.

6 IDENTIFICATION OF REGULAR POLYPEPTIDE SECONDARY STRUCTURES IN PROTEINS

As was mentioned in section 2, regular secondary structures can be identified at an early stage of a protein structure determination by NMR. This is based on the following. The sequential NOEs (see Figure 5) are dependent on the local backbone conformation and thus indicative of regular secondary structure elements.¹³ Corresponding information on the local backbone conformation comes from $^3J_{\text{HN}\alpha}$ coupling constants.¹⁵ Furthermore, when identifying sequential NOEs, all NOEs between amide protons, H- α and H- β need to be analyzed, which includes medium-range NOEs that are unique for helices and tight turns.¹⁴ This information is usually collected in a presentation of the type shown in Figure 7, where patterns of successive small $^3J_{\text{HN}\alpha}$ coupling constants and strong d_{NN} NOEs combined with the presence of

Figure 7 Standard presentation of the data used to identify regular secondary structures in proteins. The 40-residue pheromone Er-2 is used as an illustration. Below the amino acid sequence, open and solid circles identify residues with $^3J_{\text{HN}\alpha} > 8.0\text{ Hz}$, and $^3J_{\text{HN}\alpha} < 6.0\text{ Hz}$, respectively. For the sequential NOE connectivities $d_{\alpha\text{N}}$, d_{NN} , and $d_{\beta\text{N}}$ (d_{NN} , $d_{\alpha\delta}$, and $d_{\beta\delta}$ for Xxx-Pro dipeptides, $d_{\beta\text{N}}$ for Pro-Xxx), thick and thin bars indicate strong and weak NOE intensities (hatched bars indicate connectivities that were observed only at 30°C , whereas all the other data were measured at 10°C). Observed medium-range NOEs, such as $d_{\alpha\text{N}}(i, i+3)$, are indicated by lines connecting the two residues that are related by the NOE. At the bottom of the figure, ^{13}C - α chemical shifts relative to the random coil values, $\Delta\delta(^{13}\text{C}-\alpha)$, are plotted, where positive values are shifts to higher frequency and the largest shift is about 5.8 ppm. High-frequency shifts of the size observed here are indicative of helical secondary structure.²⁵ The sequence locations of three helices are identified at the bottom. (Reproduced by permission from M. Ottiger, T. Szyperski, P. Luginbühl, C. Ortenzi, P. Luporini, R. A. Bradshaw, and K. Wüthrich, *Protein Sci.*, 1994, **3**, 1515)

medium-range NOEs provide a reliable identification of helical secondary structure.¹⁴ Using additional long-range $d_{\alpha\alpha}(i, j)$ NOE connectivities and amide proton exchange data, β -sheet structures can similarly be identified.¹⁰ Recently, ^{13}C - α chemical shifts have been added as yet another indicator of regular secondary structure,²⁵ as is illustrated at the bottom of Figure 7.

Secondary structure determination is not a necessary step in a protein structure determination (see Figure 2), since the conformational constraints of Figure 7 are in any case part of the input for the structure calculation. However, it is a useful asset in several different ways. Firstly and most importantly, it may be a valuable result in itself in situations where a structure determination cannot immediately be completed. This is typical for projects where uniform or residue-selective ^{15}N labeling enables complete sequence-specific polypeptide backbone assignments via sequential NOEs (see Figure 5), but the extent of the side-chain assignments in the absence of ^{13}C labeling is insufficient as a basis for a complete structure determination. Secondly, since the covalent connections between regular secondary structure elements can be unambiguously determined, NMR secondary structure determination has been helpful in tracing low-resolution electron density maps for the determination of the corresponding X-ray crystal structure.¹⁶ Thirdly, the NMR structure determination itself may be supported in cases where NOE distance constraints are scarce during the early cycles of the structure calculation. By inclusion of supplementary dihedral angle constraints that enforce more precise formation of the regular secondary structures, convergence of the initial calculations may be improved, which in turn provides the basis for further collection of NOE distance constraints (Figure 2).

7 STRUCTURE CALCULATION FROM NMR DATA

Although complete relaxation matrix treatments of the relationships between NOEs and molecular structure have been implemented by several different groups, including ourselves,²⁶ the use of the initial-rate approximation for the NOE build-up is still representative for presently performed NMR structure calculations.¹⁰ The input data have the format of allowed distance ranges, which circumvents intrinsic difficulties that might arise from attempts at quantitative distance measurements. The lower limit is usually taken to correspond to the sum of two hydrogen atomic radii, i.e. 0.2 nm. For short-range connectivities between protons separated by not more than three single bonds in the chemical structure, that is, intraresidual and sequential distances,¹⁰ the NOE intensities are translated into corresponding upper bounds, typically in steps of 0.25, 0.30, and 0.40 nm. For longer-range connectivities, a predetermined upper limit, usually 0.40 or 0.50 nm., depending on the protein and the experimental conditions used, is applied. Unless stereospecific assignments were obtained, in particular for the β -methylene groups in amino acid side chains and the isopropyl groups of valine and leucine, correction factors for the use of pseudoatoms must be added to the upper limits on distances to prochiral groups of protons.²⁷ The resulting allowed distance ranges may then be as large as from 0.20 to about 1.0 nm. Supplementary conformational constraints, for example, from spin–spin coupling constants, are represented in the input by similar allowed ranges, which account for the limited accuracy of the measurements. In computer-supported collection of the input data, the stepwise classifications may be replaced by a smoothed fit of upper distance bounds versus NOE intensity. Furthermore, this calibration may be updated in successive cycles of the structure calculation (see Figure 2).

Distance geometry algorithms can be used to obtain the Cartesian coordinates of spatial molecular structures that are consistent with a predetermined set of intramolecular, interatomic distances.²⁸ To this end, such algorithms identify the conformations shown in equation (1),

$$\{r_i = (x_i, y_i, z_i); \quad i = 1, 2, \dots, N\} \quad (1)$$

which are consistent with inequality (2),

$$L_{ij} \leq |r_i - r_j| \leq U_{ij} \quad (2)$$

where L_{ij} and U_{ij} are lower and upper bounds, respectively, on the Euclidian distance $|r_i - r_j|$ between the points r_i and r_j , and N the number of points (or atoms) in the system studied. The problem described by inequality (2) may alternatively be expressed in the form of an error function, which can then be minimized. In the process of this conversion of distance information into Cartesian coordinates, one inevitably encounters the problem of local minima.²⁹ Metric matrix methods³⁰ and variable target functions in dihedral angle space^{31,32} have been implemented in the search for protein conformations obeying inequality (2), and the energy functions in molecular dynamics programs have been supplemented with terms representing the constraints expressed by inequality (2).^{33,34} Overall, corresponding results are obtained with these different computational approaches, although details may be subject to further analysis.

Figure 8 Illustration of an input of NOE upper distance constraints used for a high-quality NMR structure determination. The bold lines afford a stereo view of an all-heavy-atom representation of a 57-residue protein, Toxin K. Each of the 809 upper distance constraints used in the calculation of the structure is shown by a thin line connecting the two protons (or pseudoatoms) involved in the constraint. (Reproduced by permission of Walter de Gruyter from K. Wüthrich, P. Güntert, and K. D. Berndt, in 'Innovations in Proteases and their Inhibitors', ed. F. X. Avilés, Walter de Gruyter, Berlin, 1993)

Model calculations at the time of the first structure determination (see Figure 1) had shown that the quality of an NMR structure determination depends critically on the density of NOE distance constraints, while the procedure is remarkably robust with regard to low precision of the individual distance constraints.³⁵ Multiple rounds of data collection and structure calculation (see Figure 2) are usually needed to obtain the desired, high-density input (Figure 8), since many NOEs can be unambiguously assigned only by reference to an approximate molecular structure.³⁶

The result of a single distance geometry calculation (see Figure 1) represents one molecular geometry that is compatible with the NMR experiments, but it cannot tell whether this solution is unique. Thus the calculation is repeated with different starting conditions. For each calculation, convergence is judged by the residual constraint violations, and all satisfactory solutions are included in a group of conformers representing the structure of the protein. The final result of a structure determination is then commonly presented as a superposition of a group of conformers for pairwise minimum root mean square deviation (RMSD) relative to a predetermined conformer. Figure 9 shows a superposition of the polypeptide backbone in 19 conformers of the *Antennapedia* homeodomain that were selected to represent the solution structure.³⁷ The precision of the structure determination, as reflected by the dispersion among this group of conformers, varies along the polypeptide chain. From residues 9 to 58, all conformers are similar, have nearly the same overall dimensions, and contain the same secondary structure, showing that this part of the structure is well defined by the NMR data. In contrast, both chain ends are (dynamically) disordered, as is manifested by the large dispersion among the 19 conformers. Large variations are typically observed also in the precision of the structure determination of the amino acid side chains, with well defined interior side chains representing the protein core and flexibly

Figure 9 Stereo view of the polypeptide backbone of 19 energy-refined conformers selected to represent the NMR solution structure of the *Antennapedia* homeodomain. Conformers 2–19 were superimposed for pairwise minimum RMSD of the backbone atoms N, C- α , and C' of residues 7–59 with conformer 1. N and C identify the start and the end of the polypeptide chain, which comprises 68 residues. (Reproduced by permission from M. Billeter, Y. Q. Qian, G. Otting, M. Müller, W. J. Gehring, and K. Wüthrich, *J. Mol. Biol.*, 1990, **214**, 183)

Figure 10 Stereo view of the all-heavy-atom representation of an NMR conformer of Toxin K after energy refinement. The backbone atoms N, C- α , C', and O' are connected by thick lines, best-defined side chains are drawn with lines of medium thickness, and other, flexibly disordered side chains are drawn with thin lines. The locations of the first (1) and last (57) residues are identified. (Reproduced by permission of Walter de Gruyter from K. Wüthrich, P. Güntert, and K. D. Berndt, in 'Innovations in Proteases and their Inhibitors', ed. F. X. Avilés, Walter de Gruyter, Berlin, 1993)

disordered side chains located predominantly near the protein surface (Figure 10).

The individual conformers obtained as the solutions of distance geometry calculations generally contain some close interatomic contacts and correspondingly high conformational energies. These can be removed in a separate final refinement step (see Figure 2). Alternatively, in typical molecular dynamics calculations the energy minimization may be performed in concert with the fit to the distance constraints.

Structure determination with nucleic acids is pursued along similar lines as described here for proteins. As a general guide to an evaluation of the results obtained, one can assume that global folds, for example the formation of duplexes, triplexes, quadruplexes, or loops, can be well defined by NMR data. On the other hand, because of the short range and the low precision of individual NOE distance measurements, information on

details in a given nucleic acid structure type, for example bending of DNA duplexes or nonregular base stacking, may be more difficult to characterize.

8 CONCLUSION

NMR with biological macromolecules in solution has for many years been a lively field, as is amply demonstrated by numerous articles in this Encyclopedia. There are reasons to believe that this will continue to be so also in the foreseeable future, although the main interest may shift somewhat more from methods' development to the investigation of structural biology problems. Indications that a certain degree of maturity has been attained can be found in the fact that more and more commercial software for computer support of the most laborious steps in the scheme of Figure 2 is becoming available, with the promise that scientists in this field will spend more and more time on the beach while their NMR spectra are transformed into 3D structures.

1 INTRODUCTION

The overall objective of our research program in this area is to develop NMR methods to a point where they can be used to study the metal sites in diamagnetic metalloproteins. The metals of initial interest have been zinc and calcium. In the past several years we have developed and utilized Cd(II) via ^{113}Cd NMR spectroscopy as a 'spin spy' to study the Zn(II) and Ca(II) sites in metalloproteins. The reasoning behind this strategy is the fact that Zn(II) and Ca(II) have such poor spectroscopic properties since Zn(II) and Ca(II) do not have unpaired electrons and hence one cannot perform an ESR experiment. Likewise, Zn(II) and Ca(II) have closed d-electron configurations, and as a result UV-visible spectrophotometry does not provide any clearly definable transitions that could be utilized to monitor the status of ligation.

The nuclear spin of ^{67}Zn is $\frac{5}{2}$ and that of ^{43}Ca is $\frac{7}{2}$ and as such they both have prohibitively broad lines in the solution NMR spectrum. Consequently, a viable alternative is to employ a surrogate probe as a means of studying these metals in this important class of biological systems. Such a strategy demands that a great deal of care be exercised in the selection of the probe. In the case of Zn(II), Cd(II) is a natural selection. This is based on parallel chemistry and size considerations. In every case studied to date, the surrogate strategy has worked, i.e. it has provided results which are consistent with the known chemistry of the system of interest. This article outlines our efforts in support of the objective described above. Although other work is mentioned, we have made no effort for this to be a comprehensive review of ^{113}Cd NMR spectroscopy.

2 SOLUTION STATE CADMIUM-113 NMR STUDIES

The metal center of many metalloproteins plays an active role in biological function so it is important to obtain as much structural information as we can about this site. Solution state ^{113}Cd NMR spectroscopy of metalloproteins is an informative technique for studying such systems in an environment

that closely resembles that of their native state. The large chemical shift range of approximately 900 ppm of the cadmium nucleus when the metal is coordinated to the mixtures of oxygen, sulfur, and nitrogen atoms found in proteins affords a probe that can provide not only structural information but can help develop a better understanding of enzymatic mechanisms. The chemical shifts observed for cadmium-substituted metalloproteins are qualitatively consistent with the general trends found in nonbiological model systems.

An excellent review of ^{113}Cd NMR spectroscopy of small inorganic and organometallic cadmium complexes was published by Ellis in 1983.¹ The most shielding ligand is oxygen, the most deshielding is sulfur. For example, a metalloprotein whose metal center is coordinated through the sulfur atoms of thiolate groups alone will give rise to a ^{113}Cd NMR spectrum with resonances in the 600–700 ppm range, whereas signals from a Cd(II) ion that is coordinated exclusively via the oxygen atoms of carbonyl ligands will be observed between 0 and –125 ppm. The chemical shifts of those that contain a combination of nitrogen and oxygen ligands will be found in the 0–300 ppm range. Figure 1 illustrates the chemical shift ranges of a number of Cd-substituted metalloproteins and Cd complexes.

Since the technique was first published as an effective metallobioprobes of the zinc-containing proteins carbonic anhydrase and alkaline phosphatase by Armitage et al. in 1976,² ^{113}Cd NMR has been used to examine the metal center(s) of more than 20 different metalloproteins. In almost every case enzyme activity has been fully or partially retained. For a detailed description of ^{113}Cd NMR spectroscopic data on these systems, the reader is referred to a review published

Figure 1 Chemical shift ranges for Cd-substituted metalloproteins and Cd complexes. by Summers in 1988.³ A more recent approach taken in the study of metalloproteins involving ^{113}Cd NMR spectroscopy is the use of ^1H - ^{113}Cd couplings observed in 2D NMR spectra to investigate metal-ligand connectivities.⁴⁻⁶ The technique has been particularly helpful in the elucidation of the number and type of coordinating ligands at metal centers in 'zinc fingers'.⁷⁻⁹ A recent review by Coleman describes the experimental techniques used and the results obtained in greater detail.¹⁰ Here we have limited our discussion to our work on the calcium-binding proteins skeletal troponin C and concanavalin A, and to metallothionein. In addition, we will show that ^{113}Cd NMR is a suitable probe for a different type of biological system, namely the heme proteins.

2.1 Metallothionein

The only naturally-occurring protein known to bind cadmium is metallothionein (MT) and it was one of the earlier metalloproteins to be studied by solution state ^{113}Cd NMR.^{11,12} This protein was ideally suited for these purposes because of its small size (M_r ca. 6800) and more importantly because of the large number of metals that can be found in the native protein. Metallothioneins typically contain 6-9 equiv. of metals, the more common ones being zinc, cadmium, mercury, and copper. Earlier samples usually contained an inhomogeneous mixture of metals which made analysis of the ^{113}Cd NMR spectrum difficult, but the chemical shifts observed in the 550-700 ppm range indicated bridging of Cd(II) ions by cysteine thiolate groups.

The preparation of a pure $\text{Cd}_7\text{-MT}$ led to a greater understanding of the individual metal binding sites in the protein and their relationship to one another, because the ^{113}Cd chemical shift is sensitive to the small differences in the coordination environment of each of the seven sites. In addition, the spin-spin couplings observed between Cd(II) ions located at adjacent sites in the protein were used to determine that rabbit liver MT contained two separate metal clusters, one containing four metals, the other containing three. This information was unavailable prior to ^{113}Cd NMR studies because of difficulties encountered in trying to obtain a detailed X-ray crystal structure.

2.2 Skeletal Troponin C

Ellis and co-workers observed four resonances in the ^{113}Cd NMR solution state spectrum of skeletal troponin C (TnC), two of which are sharp signals and two are broad and undetectable at high fields.¹ These broad resonances are observable at lower temperatures. Research involving Ca(II) and Cd(II) titrations and equilibrium binding studies led to the assignment of the resonances to two classes of metal-binding sites. In the protein there exist two 'high-affinity' or structural binding sites and two 'low-affinity' or regulatory binding sites. The binding of Ca(II) to these regulatory sites is responsible for controlling muscle contraction.

The temperature dependence of the ^{113}Cd NMR spectrum is shown in Figure 2. At room temperature the two structural sites give rise to resonances at -107.8 and -112.7 ppm with respect to a 0.1 M solution of $\text{Cd}(\text{ClO}_4)_2$. Lowering the temperature alters the chemical exchange dynamics, resulting

Figure 2 ^{113}Cd NMR spectra of TnC at the temperatures indicated. (Reproduced by permission of the American Association for the Advancement of Science from P. D. Ellis, *Science* 1983, **221**, 1141)

in a four-line spectrum. The two new resonances at -103.1 and -109.8 ppm arise from Cd(II) bound to the regulatory sites. These chemical shift values indicate an oxygen coordination environment for each bound metal ion. However, it is the temperature dependence of the chemical shifts that is most interesting as this can be used to investigate how changes in protein conformation can be related to the occupancy of the metal sites.

2.3 Concanavalin A

Concanavalin A (Con A) is a multisubunit protein involved in carbohydrate binding. Each subunit contains two metal-binding sites; the S1 site in the native protein binds Mn(II) and the S2 site binds Ca(II). An extensive ^{113}Cd NMR study of this protein was carried out in our group and it was discovered that the protein can exist in two forms, locked or unlocked.¹³ The former gives three ^{113}Cd signals whereas the locked form has only one. It is thought that in the latter the metals are exchanging rapidly between free and bound states making the observation of bound ^{113}Cd resonances difficult.

Three resonances are observed in the ^{113}Cd NMR spectrum of the locked form at 68, 46 and -125 ppm. The signal at 68 ppm was attributed to free cadmium and it is the signal observed in the unlocked species. The others at 46 and -125 ppm were assigned to Mn and Ca sites, respectively, by simply carrying out competitive binding studies with the metals in question. Additional solution state ^{113}Cd NMR work has shown that other metals have high affinities for both the S1 and S2 site. As Figure 3 illustrates, Pb(II) displaces bound Cd(II) ions causing the ^{113}Cd resonances in the NMR spectrum to decrease in intensity and finally disappear when displacement is complete.

2.4 Heme Proteins

Cadmium-113 NMR spectroscopy has become a valuable technique for studying the role(s) of the metal(s) in predominantly calcium- and zinc-containing metalloenzymes. We will now show some data that indicate its effectiveness as a probe for a different type of biological system, namely the prosthetic group in heme-containing proteins. The function of each of these proteins is centered at the metal site in the porphyrin part of the molecule, hence ^{113}Cd NMR should be an ideal probe of these sites. In initial studies carried out in our group the model complexes used to mimic the heme site in these proteins

Figure 3 (a) ^{113}Cd NMR spectra of Cd: Cd Con A for reference. The resonances are at 68, 46, and -125 ppm. (b) The same sample after addition of 1.0 equiv. of Pb(II). (c) The same sample as (a) but with 2.0 equiv. of Pb(II) added. The resonances are at 68 and 32 ppm. (Reproduced by permission of the American Chemical Society from A. R. Palmer, D. B. Bailey, W. D. Behnke, A. D. Cardin, P. P. Yang, and P. D. Ellis, *Biochemistry*, 1980, **19**, 5063)

were cadmium-substituted porphyrins.^{14,15} Solid state methods which were employed to overcome difficulties encountered in solution state work will not be discussed here as they are reviewed in Section 3.

A single resonance at 411 ppm was observed in the solution state spectrum of ^{113}Cd protoporphyrin IX dimethyl ester (^{113}Cd -PPIXDME) at 20°C . A chemical exchange process was revealed by lowering the temperature from 20°C to -60°C . At -60°C two resonances are observed, one at 405 ppm, the other at 374 ppm. These results indicate that there are two distinct magnetic sites at the Cd(II) ion, one existing via chelation to the four nitrogens of the porphyrin's pyrrole rings, the other being a five-coordinate species in which the metal ion is axially coordinated intermolecularly to an adjacent carbonyl oxygen of a propionic ester side chain. In the solution state spectrum of ^{113}Cd -PPIX in 70:30 pyridine/aqueous KOH at 20°C , a single resonance is observed at 435 ppm whose chemical shift is also dependent on temperature. However in this case the fifth axial ligand is clearly pyridine which coordinates through a nitrogen atom.

Kennedy and Ellis first examined cadmium-substituted myoglobin (Cd-Mb) by solution state ^{113}Cd NMR in 1989.¹⁵ As in the case of the porphyrins they observed a single resonance in the NMR spectrum whose linewidth is independent of temperature, but whose chemical shift is temperature-dependent with greater shielding at higher temperatures. Cd-Mb appears to be undergoing fast chemical exchange between four-coordinate Cd-PPIX and five-coordinate Cd-PPIX axially coordinated to the proximal histidine of the globin chain.

Present work is being carried out on cadmium-substituted hemoglobin (Cd-Hb). We expect to observe a two-line spectrum for the fully substituted molecule, i.e. Cd₄-Hb where Cd(II) has replaced iron in all four heme sites. One line

may arise from Cd(II) in a four-coordinate species where Cd-PPIX is noncovalently bound in the heme pocket, and the second may arise from a five-coordinate species in which the proximal histidine donates a fifth axial ligand to the metal center.

The question arises whether or not each of these resonances can be assigned to a specific chain in hemoglobin or are they the result of the quaternary effect in the molecule? We hope to answer this question by first preparing a hybrid hemoglobin in which we will substitute only the α -chains with Cd(II) and reconstitute them with native β -chains. The ^{113}Cd NMR spectrum of such a molecule would only reflect what is happening at the metal center in the α -chain. Further experiments will involve the preparation of a series of mixed-metal hemoglobins in which we hope to exploit the sensitivity of ^{113}Cd NMR to axial bonding changes by observing the change in the chemical shift tensor when various ligands bind to the metal sites. This will involve both solution- and solid-state studies. By comparing future ^{113}Cd NMR results with the vast amount of information already available on hemoglobin, we hope to show the validity of ^{113}Cd NMR as an effective probe for the prosthetic groups present in heme proteins.

3 SOLID STATE STUDIES

A complication in the spectral analysis of solution state ^{113}Cd NMR data has been dynamical effects such as exchange averaging of the chemical shifts. There have been occasions when these processes have even prevented the observation of a resonance.^{2,11,16} Another obstacle to the interpretation of the solution state spectra is a dependence of the isotropic chemical shift on temperature, concentration, and solvent effects. One apparent answer to the problem of solution dynamics is to use supercooling to slow down the chemical exchange.¹⁷ However, this method does not resolve the other problems described previously. An alternative to the supercooled aqueous solutions is to exploit solid state NMR methods, and it is these techniques that we will focus upon here.

One advantage of using solid state NMR over solution state NMR is the extra information that can be provided. Instead of a single isotropic resonance, now all the principal elements of the chemical shift tensor are accessible. These data can be obtained by simulating a static powder spectrum and/or an analysis of MAS sideband patterns.^{18,19} Utilizing single crystal experiments, one obtains the relative orientations of the chemical shielding tensor relative to a molecular fixed coordinate system. This benefit of going to solid state NMR is exemplified in the case of cadmium-substituted porphyrin systems.^{14,15,20-22}

3.1 Heme Proteins

An example was the study of *meso*-tetraphenylporphyrin (TPP) and its pyridine adduct by Jakobsen et al.^{14,20} The first problem encountered in this investigation was that no signal in the liquid phase could be obtained from the 'unliganded' Cd-TPP. However, a ^{113}Cd spectrum of the material in the solid state could be obtained. The static powder spectrum of free 'unliganded' Cd-TPP is contrasted with that of the

Figure 4 Cross polarization (CP), solid state ^{113}Cd NMR powder spectra of (a) 'free' Cd-TPP and (b) the pyridine- ^{15}N adduct of Cd-TPP. The shielding constant (σ) scale is positive to larger shieldings and is referenced to a sample of solid $\text{Cd}(\text{ClO}_4)\cdot 6\text{H}_2\text{O}$. (Reproduced by permission of the American Chemical Society from H. J. Jakobsen, P. D. Ellis, R. R. Inners, and C. F. Jensen, *J. Am. Chem. Soc.*, 1982, **104**, 7442)

pyridine-adducted metalloporphyrin in Figure 4. The chemical shift anisotropy (CSA) of the Py-Cd-TPP is less than a third of the CSA for the free Cd-TPP, which was attributed to the axial ligand pulling the metal out of the plane of the porphyrin. If the pyridine had been bound to the cadmium without disturbing the existing structure, one would expect little change in the unique tensor element, not the 124 ppm change observed. Note that the tensor elements in the pyridine adduct move in opposite directions. Such a pattern will cause problems in the interpretation of the isotropic chemical shifts.

A logical extension of this work with metalloporphyrins came from Kennedy and Ellis in their investigation of Cd(II)-substituted heme and myoglobin.¹⁵ In that study they measured the effects of solvent and temperature on the ^{113}Cd chemical shift. The cadmium protoporphyrin IX dimethyl ester (PPIXDME) has a similar coordination of TPP and therefore a similar chemical shift tensor. Binding a pyridine axially to the Cd-PPIXDME in an attempt to mimic the histidine binding of myoglobin (Mb) shifts the ^{113}Cd resonance approximately 43 ppm in solution and not at all in the solid state. Again the tensor elements move in opposite directions. Further, from the data depicted in Figure 5, one can see that the Cd-Mb CSA has an opposite sign to that of the model, Cd-PPIXDME-Py. In considering only the isotropic shifts, one would be led to the incorrect assumption that the binding of the metal is similar in these two coordination centers. By utilizing the tensor parameters extracted from the static powder lineshapes, Kennedy and Ellis postulated that the change in CSA was in fact a measure of the strength of the axial ligand, pulling the metal further out of the plane of the heme.

An important point needs to be made with regard to these observations. Namely, the isotropic chemical shift of a metal center may be difficult to interpret because of this phenomenon of shielding tensor elements moving in opposite directions. Because of this potential problem, the solid state and liquid state methods become complementary. This situation is not unique to ^{113}Cd NMR and should be applicable to any 'heavy metal' nuclide.

Figure 5 Cross polarization, solid state, static powder 66.5 MHz ^{113}Cd NMR spectra of (a) Cd-PPIXDME (16 914 transients), 0.013 s acquisition time, 7.0 ms contact time, 3.0 s recycle delay, (b) Cd-PPIXDME-Py (9308 transients), 0.003 s acquisition time, 5.0 ms contact time, 4.0 s recycle delay, (c) Cd-PPIX (11 479 transients), 80 μs acquisition time, 5.0 ms contact time, 8.0 s recycle delay, and (d) lyophilized Cd-Mb (45 313 transients), 0.026 s acquisition time, 4.0 ms contact time, 6.0 s recycle delay. (Reproduced by permission of the American Chemical Society from M. A. Kennedy and P. D. Ellis, *J. Am. Chem. Soc.*, 1989, **111**, 3195)

3.2 Other Proteins

Some other proteins studied by solid state ^{113}Cd NMR are substituted skeletal troponin C (STnC),²³ parvalbumin from carp muscle,²⁴ concanavalin A (Con A),²⁴ and carboxypeptidase A (CPA).²⁵ Marchetti et al.²⁴ demonstrated that lyophilized proteins have considerably disordered metal-binding sites. After rehydration, the resulting protein spectra exhibit significant line narrowing and a substantial improvement in signal-to-noise ratio. A large body of work on $^{113}\text{Cd}(\text{II})$ -CPA has been done by Rivera and Ellis,²⁵ studying the protein with^{25b} and without inhibitors.^{25a} Among the complexes (inhibitors and/or substrates) investigated were 1-benzylsuccinate, glycyl-L-tyrosine, the phosphoramidite ZGP, and polypeptide potato tuber inhibitor. One major difficulty in

obtaining CP MAS spectra is that high speed spinning for an extended period tends to spin out the water, dehydrating the sample. As with the parvalbumin, the dehydration causes disordering of the cadmium resonance, and following rehydration the local structure about the metal is restored.

3.3 Cadmium Oxo Model Compounds

In order to correlate the chemical shift information with the protein structure, several model compounds were investigated. There are a vast number of solid state NMR investigations of cadmium oxo compounds in the literature.²⁶ The coordination number of cadmium in these compounds varies from six to eight, while the isotropic chemical shifts range from 150 to -100 ppm. However, the solid state data on the powders of the cadmium oxo compounds were difficult to interpret in terms of structure. In order to gain a better understanding the relationship between cadmium coordination geometry and/or number and isotropic chemical shift was to undertake a detailed study of selected cadmium oxo compounds via single crystal NMR methods.²⁷

3.3.1 Single Crystal Studies

Using single crystal NMR methods, the shielding interactions are placed in the crystal axis system. The compounds surveyed ranged from the all-oxygen environments of $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, $3\text{CdSO}_4 \cdot 8\text{H}_2\text{O}$, $\text{CdCa}(\text{OAc})_4 \cdot 6\text{H}_2\text{O}$, $\text{Cd}(\text{C}_4\text{H}_2\text{O}_4) \cdot 2\text{H}_2\text{O}$, $\text{Cd}(\text{HCO}_2)_4 \cdot 4\text{H}_2\text{O}$, and $\text{Cd}(\text{OAc})_2 \cdot 2\text{H}_2\text{O}$ ²⁸ to various mixed donor atom combinations of oxygen, nitrogen, sulfur, and chlorine.²⁹ The tensor elements of the complexes containing exclusively oxygen donor atoms are compared graphically in Figure 6. Following these investigations four correlations between tensor elements and structure have been recognized:

1. Tensor elements of like magnitude have similar orthogonal environments.
2. The most deshielded element is aligned nearly orthogonal to planes containing water.

Figure 6 Summary of the ^{113}Cd shielding tensors for cadmium oxo compounds determined by single crystal experiments. Vertical bars represent the position of individual elements relative to σ_{iso} for solid $\text{Cd}(\text{ClO}_4)_2$. The deshielded element of each tensor is designated by either a cross-hatch or a solid bar. Solid bars represent elements with intramolecular shielding contributions dominated by water oxygens. Cross-hatched elements indicate predominant short-bond shielding contributions. Sulfate suffixes correspond to cadmium in general and special positions. (Reproduced by permission of the American Chemical Society from R. S. Honkonen, and P. D. Ellis, *J. Am. Chem. Soc.*, 1984, **106**, 5488)

3. If water oxygens are not present in the coordination sphere, the least shielded element is oriented to maximize the shortest Cd–O shielding contributions.
4. The most shielded tensor element is nearly perpendicular to the longest Cd–O bond.

These empirical rules have been extended by other groups to additional model compounds,^{26e,30} some with mixed atom donors to cadmium, such as cadmium–sulfur or cadmium–selenium coordination systems by Santos et al.³¹ and others.³² In each case, the applicable paradigms have proven to be generalized to these other ligand systems.

3.4 Mixed Donor Atom Combinations

Barrie et al.³⁰ explored some nitrogen and oxygen mixed coordination to cadmium using bisglycinatocadmium(II) monohydrate and bis-L-alaninatocadmium(II) trihydrate. Both of these compounds are nearly octahedral with N_2O_4 coordination about the cadmium. The solid state spectra of these compounds exhibit fine structure due to a dipolar coupling between ^{113}Cd and ^{14}N , which Barrie has utilized to determine the number of nitrogen atoms coupled to the cadmium. As in the case of ligated Cd(II) in PPIXDME and myoglobin,¹⁵ the ^{113}Cd isotropic chemical shifts of bisglycinatocadmium(II) monohydrate and bis-L-alaninatocadmium(II) trihydrate determined by Barrie and co-workers³⁰ are identical, yet the principal components of the shielding tensor are very different. This again illustrates the power of multiphase NMR investigations with so-called ‘heavy’ nuclides such as ^{113}Cd , as the sensitivity of the shielding tensor to changes in geometry (internuclear distances and orientations within the crystallite) shows.

3.4.1 Poly(pyrazolyl)borates

To confirm that compounds with donor atoms other than oxygen follow the patterns laid out by the cadmium oxo study, an extensive series of models using nitrogen donor atoms is being undertaken. The family of ligands being utilized are the poly(pyrazolyl)borates, whose chemistry with cadmium is only now being fully explored. Other model compounds such as cadmium diimidazole diacetate, which has been the only model employed in the interpretation of ^{113}Cd -substituted carboxypeptidase-A (CPA), tend to polymerize.³³ This polymerization generates a significantly different structure from that of the CPA, making the interpretation of the ^{113}Cd shielding tensor data of CPA difficult. The bulky nature of the pyrazolylborates makes them ideally suited to generate monomeric complexes with nitrogen donor atoms. A few studies using pyrazolylborates as models for histidine coordination to copper have already appeared in the literature.³⁴

The basic structure of the poly(pyrazolyl)borate ligands coordinated to cadmium is depicted in Figure 7. These ligands are extremely versatile because the number of donor atoms can be varied in going from the dihydrobis-, hydrotris-, to tetrakis(pyrazolyl)borate. By altering the poly(pyrazolyl)borate ligand, one can control the core atoms to range from N_4 to N_6 and several mixed-ligand donor atom combinations (i.e., N_5 , N_3S_2 , N_3O_2 , N_3H_2 , N_3C , and N_3H).³⁵

The initial solid state NMR study of these complexes with four- and six-coordinate nitrogen donors allowed a comparison with porphyrin coordination and a correlation between ligand

Figure 7 General structures of some poly(pyrazolyl)borate ligands bound to a cadmium; (a) dihydrobis(pyrazolyl)borate, (b) hydrotris(pyrazolyl)borate, and (c) tetrakis(pyrazolyl)borate. The R groups are in the 3-position and the R' groups are in the 5-position of the pyrazolyl rings, where R and/or R' can be H, Me, *t*-Bu, or Ph. (Reproduced by permission of the American Chemical Society from A. S. Lipton, S. S. Mason, D. L. Reger, and P. D. Ellis, *J. Am. Chem. Soc.*, in press)

geometry and the shielding tensor.³⁶ To facilitate interpretation of protein data, a further expanded basis set of model compounds is needed. Toward this end, several five-coordinate complexes with mixed donor atoms were also studied,³⁷ as well as some four-coordinate alkyl derivatives.³⁸ The principal components of the shielding tensors derived for a sampling of these complexes are presented in Figure 8. Other interesting complexes generated with pyrazolylborate chemistry were a cadmium hydride and the first reported cadmium–cadmium bond.^{35c}

The poly(pyrazolyl)borate ligands are indeed well suited for studying cadmium coordination chemistry and chemical shielding effects. Minor changes, such as methylation of the pyrazolyl rings of the ligand, can lead to large variations in the elements of the shielding tensor, while leaving differences in the isotropic shifts relatively small. These minor changes in

Figure 8 Sampling of the ^{113}Cd shielding tensors derived from the CP MAS spectra of several poly(pyrazolyl)borate cadmium complexes. The core donor atoms given are the atoms bound to the metal center. The chemical formulas of the compounds, from top to bottom, are as follows: $[\text{B}(\text{pz})_4]\text{Cd}$, $[\text{B}(3\text{-Mepz})_2]\text{Cd}$, $[\text{HB}(3,5\text{-Me}_2\text{pz})_3]\text{Cd}$, $\text{Cd}[\text{HB}(3\text{-Phpz})_3]^+\text{Bu-acac}$, $[\text{HB}(3,5\text{-Me}_2\text{pz})_3]\text{Cd}[\text{H}_2\text{B}(\text{pz})_2][\text{HB}(3,5\text{-Me}_2\text{pz})_3]\text{Cd}[\text{S}_2\text{CN}(\text{Et})_2][\text{HB}(3,5\text{-Me}_2\text{pz})_3]\text{CdBH}_4$, and $[\text{HB}(3,5\text{-Me}_2\text{pz})_3]\text{CdMe}$ (where pz = pyrazolyl). The chemical shifts are referenced to an external sample of a 0.1 M solution of $\text{Cd}(\text{ClO}_4)_2$

similar ligands can be utilized to tailor the model compounds to approximate more closely the metal environment of a protein.

4 SUMMARY

To date the surrogate probe strategy has worked well. However, great care has to be exercised at all times. We are currently pursuing the ab initio calculation of ^{113}Cd chemical shifts.³⁹ Our data base of shielding tensor data should provide excellent benchmarks for a comparison between theory and experiment. Such calculations should provide unambiguous correlations between chemical shielding and structure. Such relationships are essential to further our understanding of the role of metals in metalloproteins.

Acknowledgments

During his years at USC (where most of this research was carried out), P.D.E. enjoyed the support of many of his colleagues, faculty, postdoctorals, and graduate students, and wishes to thank them for their support through the years. Further, this work could not have been accomplished without the financial support of the National Science Foundation and the National Institutes of Health. For their support P.D.E. is grateful. The authors would also like to acknowledge additional support from Battelle Pacific Northwest Laboratories.

Biographical Sketches

Kate McAteer. *b* 1968. B.Sc., 1990, University of Ulster, Northern Ireland, UK. Graduate student, University of South Carolina, 1990–93. Currently continuing graduate research under the direction of P. D. Ellis at Battelle Pacific Northwest Laboratories. Research interests: ^{113}Cd NMR of Cd-substituted hemoglobins, ultrahigh field NMR studies of DNA oligomers.

Andrew S. Lipton. *b* 1965. B.S., 1987, Ph.D., 1993, Chemistry, University of South Carolina. Spent approximately two years as a laboratory technician for George C. Levy and Philip N. Borer at Syracuse University before undertaking Ph.D. research under the guidance of Paul D. Ellis. Current research interests: solid state NMR of cadmium model complexes and quadrupolar nuclides.

Paul D. Ellis. *b* 1944. B.S., 1966, Ph.D., 1970, Chemistry, University of California at Davis. Assistant, associate, and George H. Bunch, Sr. Professor of Chemistry, University of South Carolina, 1970–93; Associate Director, Macromolecular Structure and Dynamics Group, Battelle Pacific Northwest Laboratories, 1993–present. Approx. 150 publications. Current research interests: heterogeneous catalysis, structural biology.

Calcium-Binding Proteins

1 INTRODUCTION

Although the occurrence of calcium in mammalian bone, sea shells, and other mineralized tissue was established shortly after the discovery of calcium as an element, the fundamental role of Ca^{2+} ions as regulators in a wide variety of cellular processes was perceived only recently. Today several hundred calcium-binding proteins [CABPs] have been identified in biological tissue,¹ but details of their biological function is known only for a minor fraction. Merely a handful have so far been subjected to extensive NMR studies. Before we embark on a survey of these studies and what type of information they have yielded, we will attempt very briefly to highlight some basic properties of CABPs and their biological distribution.

In eukaryotic cells, a large number of activities are governed by the intracellular concentration of Ca^{2+} ions. In a resting cell, the free Ca^{2+} concentration is ca. 100–200 nM. In contrast, the extracellular concentration is of the order of a few mM.² As a result of some hormonal stimulation at the outer cell surface, the intracellular Ca^{2+} concentration is rapidly (ms timescale) increased by a factor of 10^3 – 10^4 . This increased level may be the result of influx from the extracellular milieu but more likely from intracellular Ca^{2+} stores, for example the sarcoplasmic or endoplasmic reticulum. Present in eukaryotic cells are also a number of specific regulatory CABPs, often with several putative Ca^{2+} binding sites with an affinity for Ca^{2+} such that in a resting cell these sites will be largely unoccupied ($K_a \simeq 10^5$ – 10^6 M^{-1}). At the increased Ca^{2+} level they will, however, be nearly fully occupied. In response to Ca^{2+} -binding, these proteins may undergo conformational changes, for example exposure of hydrophobic surfaces, that cause them to form complexes with, and influence the biological activity of, various enzymes. Among the most well known and studied regulatory CABPs of this type are calmodulin [CaM; $M_r = 16\,700$] and troponin C [TnC; $M_r = 18\,000$]. The former is a highly conserved protein found in all eukaryotic cells, while the latter is observed in

muscle cells in a complex with two other proteins, troponin I (TnI) and troponin T.

The Ca^{2+} -binding sites in CaM and TnC consist of a structural motif called the EF-hand, which consists of α -helix–‘loop’– α -helix. The central 12-residue sequence contains the calcium coordinating residues, is highly conserved, and comprises a loop and short segments of the flanking α -helices. The EF-hand motif was first identified³ in the crystal structure of a CABP with high Ca^{2+} affinity called parvalbumin [PV; $M_r = 12\,000$]. EF-hands occur in pairs in CaM, TnC, and a large number of other CABPs, and cooperative Ca^{2+} binding has been established in many cases. Some 20 subfamilies of EF-hand proteins have been described.⁴ One of these, the S-100 subfamily, contains a variant hand with two extra amino acids in the loop. Members appear in widely different cell types and include the vitamin D₃-induced proteins calbindin D_{9k} [CB-9; $M_r = 8700$], the cystic fibrosis antigens MRP-8 and MRP-14, and the proteins that gave the name to the subfamily, S-100a and S-100b.^{5,6} The biological function of the S-100 proteins is far from established and subject to intense studies. Among the many CABPs in the central nervous system, the three EF-hand proteins calbindin D_{28k} (CB-28), calretinin, and PV are particularly striking in their abundance and in the specificity of their distribution in different cell types.^{7,8}

Important non-EF-hand intracellular CABPs include the annexins, which interact with phospholipid membranes and are presumed to promote membrane fusion,⁹ and the highly acidic proteins calsequestrin and calreticulin that serve as weakly chelating ‘buffers’ for Ca^{2+} ions in the Ca^{2+} -rich organelles SR and ER, respectively.¹⁰

If we now look at the extracellular milieu, we find new roles for Ca^{2+} . Several proteolytic enzymes of the serine protease type, e.g. trypsin, elastase, etc., have a moderately strong Ca^{2+} -binding site ($K_a \simeq 10^3$ – 10^4 M^{-1})¹¹ that is occupied under the prevailing Ca^{2+} concentration. The Ca^{2+} ion is here coordinated with ligands from different parts of the protein.¹² It is not part of the active site but appears to have a general stabilizing role. The Ca^{2+} ion is however part of the active site in another enzyme, phospholipase A₂ (PPASE),¹³ where it plays a role in the mechanism of the catalyzed reaction.¹⁴

Blood coagulation—so essential to human survival—is a carefully regulated cascade of molecular events involving many proteins and dependent on the presence of Ca^{2+} ions.¹⁵ Several of these proteins are built up of many domains, some of which contain the amino acids γ -carboxyglutamic acid (Gla) and β -hydroxylated aspartic acid (Hya) or asparagine (Hyn).

Bone is a remarkable composite of inorganic (calcium hydroxyapatite) and organic constituents.¹⁶ A number of Gla containing CABPs in the organic matrix have been described: osteocalcin [$M_r = 5\,300$], the matrix Gla protein [$M_r \simeq 10\,000$], the acid glycoproteins osteonectin [apparent $M_r = 32\,000$], and thrombospondin [$M_r = 150\,000$ per monomer].¹⁷

Although the intracellular Ca^{2+} levels in some prokaryotic microorganisms such as *E. coli* appear to be strictly regulated,¹⁸ little is presently known about their CABPs. At the time of writing, only one prokaryotic protein with a proper EF-hand has been described: calerythrin from *S. erythraea* [$M_r = 20\,000$].^{19,20} Interestingly, however, the D-galactose-binding protein in the periplasmic space of *E. coli* is found to have a Ca^{2+} site in which the ligand arrangement is virtually identical

to that of an EF-hand, although the ligands are presented by amino acids from different parts of the protein.²¹ It is clear that Ca^{2+} ions are also important for the structural integrity of many prokaryotic proteins, in some cases acting merely as a stabilizing entity, but in other cases required for enzymatic activity as in staphylococcal nuclease (NASE).

NMR studies of CABPs have been concerned with a wide variety of problems: solution structures and dynamics, interactions with other molecules and ions, binding affinities and chemical exchange rates, as well as the detailed nature of the cooperativity of Ca^{2+} binding observed for many proteins. The large amount of work performed on CaM is covered in a separate chapter in this Encyclopedia (*Calmodulin*) and will only be mentioned in passing here.

2 SOLUTION STRUCTURES OF CABPs IN THE PRESENCE AND ABSENCE OF Ca^{2+}

In early NMR studies, structural information was mainly obtained from a limited set of the available NMR observables. For example, the chemical shift displacement of ^1H NMR resonances upon binding of metal ions to CB-9 provided some insight into the metal ion induced conformational changes.^{22,23} The replacement of Ca^{2+} with Yb^{3+} to induce paramagnetic shifts for ^1H resonances from residues in the vicinity of the ion-binding sites enabled Sykes and co-workers to infer very minor differences in the structure of different PVs.^{24,25} Substitution of Gd^{3+} for Ca^{2+} can provide distance information based on the paramagnetic relaxation line broadening of protein ^1H resonances; this strategy was applied to a 13-residue synthetic peptide comprising site III of TnC in conjunction with comparisons with crystal structures.²⁶ PhotoCIDNP experiments have been employed in order to study the environment around individual residues in different forms of PV²⁷ and different states of CB-9.²³

The next level of structure information, short of a full three-dimensional structure determination, is provided by studies that involve careful analyses of a large number of NMR parameters, in particular NOEs, enabling characterization of the secondary structure elements and the overall fold of the protein. In this fashion, the solution structure of Ca^{2+} -loaded PV has been described.²⁸ Comparative studies of CB-9 in several different states have been presented at this level of detail,^{29–32} providing information on the structural and dynamical changes that occur upon binding of ions, and insights into the molecular basis for cooperative Ca^{2+} binding. The Edmonton groups have in a series of studies assessed the solution conformations of synthetic polypeptides comprising individual binding sites, as well as hetero- or homodimers of the C-terminal EF-hand domains of TnC.^{33–35}

Three-dimensional solution structures have been reported for several CABPs, in some cases for both the Ca^{2+} -free and Ca^{2+} -bound states. A medium-resolution structure has been presented for native, porcine $(\text{Ca}^{2+})_2\text{-CB-9}$,³⁶ showing a very close similarity to the crystal structure of the bovine protein. High-resolution solution structures of three different states of bovine CB-9 [$(\text{Ca}^{2+})_2$, $(\text{Cd}^{2+})_1$, and apo] have been determined,^{37–39} allowing comparisons with the crystal structure as well as between the different solution structures. These studies thus provide detailed information on the

structural changes that occur upon ion binding. A remaining problem with NMR-derived structures of EF-hand proteins is that the loop regions—which may be of central interest to the researcher—are among the least well defined parts of the protein because of their exposed location in the structure and consequent lower number of NOE contacts with the rest of the protein. However, the attainable precision of the ion-binding loops is high enough that the differences between the loop conformations of standard and pseudo-EF-hands can readily be distinguished, as further demonstrated for the solution structures of two CB-9 mutants with modified calcium-binding sites.⁴⁰ It is possible that future structural studies that utilize heteronuclear coupling constants to a larger extent may alleviate this inherent problem, and improve the definition of the loop structures; alternatively, constraints between the calcium ions and the protein that have been inferred from crystal structures can be included in the calculations. The latter strategy was used in the structure determination of a homodimer of the fourth EF-hand domain of TnC,⁴¹ yielding rather well defined ion-binding loops. Three-dimensional structures have also been calculated for the homodimers of synthetic EF-hands comprising site III in TnC.⁴² Other EF-hand proteins for which high-resolution NMR structures will soon appear include recoverin, which is a Ca^{2+} sensor in vision,⁴³ and calcineurin B, which has four EF-hands and is highly homologous to CaM,⁴⁴ and a fragment comprising the two N-terminal EF-hands in CB-28.⁴⁵

The interactions between regulatory CABPs and their targets is a subject of much interest. The NMR-derived structure of a CaM–peptide complex is discussed in the *Calmodulin* article. An application of transferred NOEs enabled the structure determination of a synthetic inhibitory peptide from troponin I (TnI) complexed to skeletal muscle TnC, showing that the peptide binds to a hydrophobic surface on TnC that becomes exposed upon binding of calcium.⁴⁶

Turning to CABPs outside of the EF-hand family, high-resolution structural studies have been described for the EGF-like domains of coagulation factor IX in the Ca^{2+} -free state⁴⁷ and factor X in both the Ca^{2+} -free and Ca^{2+} -loaded states.^{48,49} Direct structural identification of the Ca^{2+} site was thus achieved for the EGF-like domain of factor X. In distinct contrast to the EF-hand proteins, here the Ca^{2+} site is located in a cleft between structural elements (a two-stranded β -sheet and the extended N-terminal segment of the domain) that have a large number of NOE contacts, resulting in a quite well-defined calcium-binding site in these solution structures (see Figure 1).⁴⁹ Another interesting structural study is that of the acyl carrier protein—a small protein with two sites, each capable of binding Mg^{2+} or Ca^{2+} . In this case the solution structure was first determined in the presence of Ca^{2+} ions using ^1H NMR.⁵⁰ The location of the divalent cation sites was then determined using relaxation perturbed 2D NMR spectroscopy on a protein with the paramagnetic Mn^{2+} ion as a substitute for Ca^{2+} , an experiment that yields ion–proton distances in the range 3.0–9.0 Å.⁵¹ The solution structure of NASE (149 residues) has been determined in the presence of Ca^{2+} and an inhibitor using ^1H , ^{13}C , and ^{15}N NMR,⁵² and structural consequences of Ca^{2+} and inhibitor binding were inferred from chemical shift comparisons between the bound and free forms of the protein.⁵³ The solution structure of a 173 residue CABP of the soil bacterium *M. xanthus*, named protein S, has recently been solved using multidimensional

Figure 1 Stereo drawing of the calcium-binding site of the N-terminal EGF module in factor X, as determined by ^1H NMR. Side chains that are unambiguously identified as calcium ligands are shown in gold with the calcium coordinating oxygens in red, and a potential ligand is drawn in pale green with the oxygens in brown. Reprinted from Selander-Sunnerhagen et al. with permission of the American Society for Biochemistry and Molecular Biology, Inc.

heteronuclear MR spectroscopy on a ^{13}C - and ^{15}N -labeled sample.^{54,55} A recent low-resolution structure of a 32 residue fragment from annexin I bound to micelles⁵⁶ shows promise for further studies of membrane-bound CABPs.

3 DYNAMIC PROPERTIES OF CABPs

A large body of work shows a marked difference in thermodynamic stability between the calcium-saturated and calcium-free forms of CABPs.^{57,58} An interpretation of this could be that in the presence of Ca^{2+} the protein largely prefers one conformation, while in the absence of Ca^{2+} the protein samples a larger volume of the conformational space. NMR spectroscopy has been used to address these questions by studying the dynamical properties of CABPs. Two principal techniques have been used covering the motional timescales of ps–ns (heteronuclear relaxation measurements) and ms and longer (amide proton exchange studies), respectively. At the time of writing, CB-9 is the CABP for which the dynamics on these two timescales has been most extensively studied for several different ion ligation states. In addition, other parameters such as aromatic ring flip rates³⁰ and chemical shift differences between side chain methylene protons for calcium-ligating residues⁵⁹ have been reported to show that the apo form of this protein has a higher internal mobility than the calcium-loaded state. These studies will therefore be covered in some detail in the following.

Amide proton exchange rates have been measured for three forms of CB-9; apo, $(\text{Cd}^{2+})_1$, and $(\text{Ca}^{2+})_2$.^{31,60,61} Both direct $^1\text{H} \rightarrow ^2\text{H}$ exchange of slowly exchanging amide protons and

indirect proton exchange via saturation transfer from water to rapidly exchanging amide protons were studied. The addition of Ca^{2+} or Cd^{2+} was found to retard the exchange of many amides over the whole protein indicating a reduction in the molecular flexibility. These marked changes in dynamical properties of CB-9 stand in stark contrast to the minute structural changes upon ligation of calcium. The hydrogen exchange rates also show that the reduction in flexibility is largest for the first binding step. This observation implies a larger positive contribution to the free energy of the system in binding of the first ion than the second, partly explaining the positive cooperativity observed in the binding of calcium ions to CB-9.³¹ A remark is in place here. Positive cooperativity implies that the free energy change associated with binding a calcium ion to a site is more negative if the other site is already occupied. The free energy change is thus less negative, or more positive, if the other site is empty. Grzesiek and Bax have recently presented a rapid and sensitive 2D NMR approach for measuring exchange rates and NOEs with water for rapidly exchanging amide protons. They have applied their technique to calcineurin B for which they have found that, in analogy with CaM, the long α -helix is not rigid in solution.⁶²

The first ^{15}N -relaxation study involving the majority of the backbone amide nitrogens was presented for NASE in the presence of Ca^{2+} and inhibitor.⁶³ This study involved measurements of ^{15}N spin–lattice (R_2) relaxation rates as well as $\{^1\text{H}\}$ - ^{15}N NOEs. These data were analyzed using a model-free formalism incorporating the overall rotational correlation time, a generalized order parameter (S^2), and an effective internal correlation time for each amide group. The NASE study suggests that there is no correlation between the rapid small amplitude motions and location of secondary structure elements in this enzyme. Inconsistency in the analysis of some of the NASE data led to the development of an extended model-free formalism in which two distinct internal motions are incorporated.⁶⁴ Carbon-13, R_1 , R_2 and $\{^1\text{H}\}$ - ^{13}C NOEs have been measured for leucine methyl groups in NASE using a labeled preparation of the protein. In these studies significant changes in the R values were observed for methyl groups close to the ligand-binding site upon addition of inhibitor.⁶⁵ Nitrogen-15 relaxation rate measurements have also been made for three states of CB-9: apo, $(\text{Cd}^{2+})_1$, and $(\text{Ca}^{2+})_2$.^{66,67} In the $(\text{Cd}^{2+})_1$ and $(\text{Ca}^{2+})_2$ states the helices and calcium-binding loops have very similar order parameters ($S^2 \simeq 0.8$) indicating similar amplitudes of motion. However, the linker region joining the two EF-hands shows a substantially higher flexibility in all three forms of the protein. This study identifies the origin of the low structural definition in this linker region as structural disorder while the reason for the structural uncertainty in the calcium-binding loops of the ion-loaded states is a byproduct of methodological shortcomings rather than a dynamical phenomenon,⁶⁶ (see Figure 2). It was also found that the two binding loops respond differently to metal-ion ligation. The N-terminal ion-binding loop (the pseudo EF-hand) does not change its high frequency (10^9 – 10^{12} s^{-1}) fluctuations upon ligation, while residues G57–E60 in the C-terminal binding loop have significantly lower order parameters in the apo state than in the metal-bound states.⁶⁷ These results show that dynamical processes on the ps–ns timescale also contribute entropically to the cooperative phenomenon of calcium-binding for the pathway in which the first ion binds to the C-terminal site.

Figure 2 (Opposite) Comparison of structural definition (a) and dynamical properties on the ps–ns timescale (b) for calcium-loaded CB-9 in solution.⁶⁶ In (a) the α -carbon trace is shown for 33 structures that are overlaid using backbone atoms. The termini, calcium-binding loop regions, and linker region show structural dispersion. In (b) the ^{15}N order parameter, S^2 , has been mapped in color onto the average structure. Red represents flexible regions and blue represents more rigid regions. Only the linker region and the C-terminus show enhanced flexibility on the ps–ns timescale

Of considerable interest also are the studies of amide proton exchange and ^{15}N NMR relaxation in CaM as well as CaM complexed with peptides from the CaM binding site on the myosin light chain kinase as covered in the article by Ikura (*Calmodulin*).

4 CHEMICAL EXCHANGE RATES AND METAL ION BINDING CONSTANTS

Chemical exchange rates and Ca^{2+} -binding constants can be determined by NMR in a straightforward manner when their values fall in certain ranges. Calcium ion dissociation rates can be deduced from lineshape analysis as a function of temperature or amount of added metal ion. The accessible range normally covers from 50 to 10^4 s^{-1} . Measurements of equilibrium binding constants can be achieved by stepwise additions of metal ion to the apo protein followed by recording the NMR spectra at each step. The range of binding constants that can be covered is given by the protein concentrations that are possible to use, since both the bound and free ion have to constitute a distinguishable fraction of the total ion concentration, at least at some points in the titration. Protein concentrations above 1–10 mM often cause aggregation, whereas the signal-to-noise ratio of the NMR spectrum might be unreasonably low at concentrations below 30–100 μM , even for proton NMR. The binding constant

range that can be covered with NMR therefore seldom exceeds $1\text{--}10^6 \text{ M}^{-1}$.

The assessment of the binding constant involves computer fitting to a spectral parameter as a function of total ion concentration. The spectral parameter of choice is one that can be obtained with good precision throughout the titration and is significantly different in the apo and metal ion bound states. In the case of slow exchange, one usually follows the intensity of a signal that either increases or decreases throughout the titration, whereas in the case of fast exchange it is common to follow the chemical shift of a resonance which is shifted as a consequence of ion binding. When metal ion NMR is used, the parameter of choice is often the signal linewidth which, in the case of fast exchange, decreases during the course of titration. The observed value of the spectral parameter, X , at each titration step, is given by

$$X = (p \cdot X_{\text{Ca}} + [1 - p] \cdot X_{\text{apo}}) \cdot F \quad (1)$$

where X_{Ca} and X_{apo} are the parameter values in the calcium-bound and -free states, respectively, and p is the fraction of protein that has bound calcium. The quantity p is given by the total calcium concentration, total protein concentration, and the equilibrium binding (association) constant K_a . When the observed parameter is affected by dilution as a consequence of ion additions (as for signal intensities), F is the initial volume divided by the volume at the particular titration step. Otherwise

(as for chemical shifts and linewidths), $F = 1$ throughout the titration.

Excellent examples of this kind of treatment are given in studies of calcium binding to the EGF-like domain in the blood clotting factor X,⁶⁸ peptide analogs of EF-hand calcium-binding sites,^{69,70} PPASE,⁷¹ as well as to CB-9 mutants in which the affinity for one of the two sites is markedly reduced.⁷² In those cases where the protein contains additional sites with affinities within two orders of magnitude from that of the site of interest, the accuracy of the deduced binding constant is much increased if the additional site(s) are taken into account.^{73,74} A large number of NMR studies have been devoted to determination of Ca^{2+} affinities of CABPs and the references cited herein constitute just a subset.

In cases where many sites have similar affinities, NMR studies offer the unique possibility of distinguishing ion binding at separate sites and thus provide a measure of the relative affinities of those sites, even in those cases where the absolute affinities are too high to be measured by NMR. Such approaches have been used to study cation exchange at separate sites in PV⁷⁵ and oncomodulin.⁷⁶ Combined data from Ca^{2+} titrations monitored by ^1H NMR and competition with a chromophoric chelator have made it possible to assess quantitatively the free energy of interaction between binding events at the two sites in CB-9 wild-type as well as charge-substitution mutants.⁷⁷ Calcium ion titrations as followed by ^1H NMR are also very useful in assessing which sites are affected by certain mutations, as in CaM.⁷⁸ The calcium-binding process of CaM has in fact been more extensively studied than that of any other protein, although, or maybe because, the presence of as many as four calcium sites precludes straightforward extraction of conclusive results. A breakthrough in the studies of CaM has been the use of tryptic fragments, which comprise the two globular (two-site) domains. Comparable experiments on both these fragments and intact CaM has made it possible to identify which domain contains the strong and weak calcium sites, respectively,⁷⁹ and to assign Ca^{2+} off-rates to separate sites.⁸⁰ Similar studies on the structurally homologous protein TnC also include the effect of added Mg^{2+} on Ca^{2+} -exchange rates.⁸¹ A more complete picture of Ca^{2+} -binding studies of CaM is given by Ikura (*Calmodulin*).

5 DIRECT OBSERVATION OF $^{43}\text{Ca}^{2+}$ SIGNALS FROM Ca^{2+} BOUND TO CABPs

An alternative way of using NMR in the study of the interactions between a protein and a metal ion is to observe directly the NMR resonance(s) for an NMR-active isotope of the metal ion and how the binding to the protein will perturb different NMR parameters. The only naturally occurring calcium isotope amenable for NMR studies is ^{43}Ca ($I = \frac{7}{2}$; $eQ = -0.05 \times 10^{-28} \text{ m}^2$). Its natural abundance is only 0.145% and it has a magnetogyric ratio such that the NMR frequency is 33.5 MHz at $B_0 = 11.7 \text{ T}$. Most, if not all, biological applications of ^{43}Ca NMR have been made with isotope-enriched samples—usually 40–60%. Although ^{43}Ca is a quadrupolar nucleus, its quadrupolar moment is relatively

small and under conditions such that the effective electric field gradient at the nucleus is modest, its relaxation rate is low. In dilute aqueous solutions of calcium salts it is of the order of 1 s^{-1} ,⁸² while in binding sites of near octahedral symmetry in moderately large proteins the transverse relaxation rate is observed to be of the order of 10^3 – 10^4 s^{-1} (cf. further below). While in the case of rapid isotropic motion, the transverse and longitudinal relaxation rates of a spin $I = \frac{7}{2}$ nucleus are equal and follow a single exponential, the situation becomes more complex in the case of slow isotropic motion—a situation that might prevail in a protein-binding site. Here the relaxation is no longer exponential, but the weighted sum of four exponentials. In addition, the NMR signals may be affected by a phenomenon called second-order dynamic frequency shifts. Thanks to efforts by Bull, Halle, Hubbard, Wennerström, Werbelow, Westlund, and others the theoretical framework, and its practical implications in biological applications, is now well advanced.^{83–88} For a comprehensive outline, see Forsén et al.⁸⁹

Early applications of ^{43}Ca NMR to the study of CABPs were concerned with systems in which the Ca^{2+} ions were in stoichiometric excess and in fast chemical exchange between ‘free’ and protein-bound states. Through the combined use of isotope-enriched samples, high magnetic fields, specially designed probes and FT NMR using pulse sequences intended to minimize probe ringing at low NMR frequencies, around 1980 it also became possible to observe ^{43}Ca NMR signals from ions firmly bound to millimolar concentrations of CABPs.^{90,91} The signal-to-noise ratio was sufficiently high to permit measurements of the longitudinal relaxation rates ($R_1 \approx 10^3 \text{ s}^{-1}$). But more important was the fact that the temperature dependence of the ^{43}Ca NMR lineshape in many systems was quite considerable and allowed rather precise determinations of chemical exchange rates of the Ca^{2+} ions under equilibrium conditions.⁹² The chemical shift of $^{43}\text{Ca}^{2+}$ ions bound to EF-hand sites is found to be about 10 ppm to high-frequency of the shift of ‘free’ Ca^{2+} ions, meaning that the NMR signal from Ca^{2+} ions in stoichiometric excess will show up as a separate, usually very narrow, resonance. In non-EF-hand proteins the free and bound signals may overlap, but it has been found that anionic lanthanide shift reagents, e.g. $\text{Dy}(\text{PPP})_2$,⁷ may displace the free signal away from the position of the bound ion(s).⁹³

In summary, ^{43}Ca NMR can be profitably used in the study of CABPs to obtain information about binding constants in the range 1 – 10^4 M^{-1} , rates of exchange of Ca^{2+} ions in the range $k_{\text{off}} \approx 10$ – 5000 s^{-1} , pK_a values of groups responsible for Ca^{2+} binding, and the competition of other cations or small molecules for the Ca^{2+} site(s) or the influence of these on dynamic parameters. An overview of the methodology and performed studies was recently given.⁹⁴ The ^{43}Ca NMR spectra in Figure 3 are taken from a publication which describes the combined use of ^{43}Ca NMR, ^{113}Cd NMR (cf. below), and stopped flow to assess structural and dynamic properties of the calcium-binding site in bovine serine proteases and their zymogens.¹¹

6 ^{111}Cd , ^{113}Cd , AND OTHER SUBSTITUTION PROBES

Cadmium has two isotopes that are amenable to NMR studies— ^{111}Cd and ^{113}Cd , of which the latter has been

Figure 3 ^{43}Ca NMR spectra at 24.34 MHz of (a) 2 mM tosyltrypsin and 2.5 mM $^{43}\text{Ca}^{2+}$ and (b) 1 mM tosyltrypsinogen and 1.3 mM $^{43}\text{Ca}^{2+}$. In both spectra the sharp signal at 0 ppm corresponds to free $^{43}\text{Ca}^{2+}$ ions and the broad signal to protein-bound $^{43}\text{Ca}^{2+}$. A 30 Hz line-broadening function was used to enhance the signal to noise ratio. Redrawn after Chiancone et al.¹¹ with permission of Academic Press Inc. (London) Ltd

extensively used as a Ca^{2+} -substitution probe in NMR investigations of CABPs. (See *Cadmium-113 NMR: A Surrogate Probe for Zinc and Calcium in Proteins*.) Since both ^{111}Cd and ^{113}Cd are a spin- $\frac{1}{2}$ nuclei, they give much sharper NMR resonances than the quadrupolar ^{43}Ca nucleus. The chemical shift range for $^{113}\text{Cd}^{2+}$ bound to proteins covers about 1000 ppm and the chemical shift is highly sensitive to the number, nature, and disposition of the metal-coordinating ligands. In addition, the ionic radius of Cd^{2+} is similar to that of Ca^{2+} , and the site preferences are often the same for the two ions. An exception to this rule is CB-9 in which the two sites bind calcium with similar affinity, whereas cadmium is bound first at the C-terminal site.⁹⁵ Therefore, ^{113}Cd NMR provides a parameter indicative of the extent of site-site interaction; the chemical shift displacement of the $^{113}\text{Cd}^{2+}$ ion bound to the C-terminal site as a consequence of cadmium entering the N-terminal site.⁹⁵ Mutational studies have shown that there

is a high correlation between the value of the chemical shift displacement and the free energy of interaction between the sites.^{77,96} For this particular protein, ^{113}Cd NMR has been extensively used in the assessment of structural perturbations caused by mutations in and around the calcium sites.^{97,98} Studies of this and several other EF-hand proteins, e.g. CaM,⁹⁹ skeletal^{81,100} and cardiac¹⁰¹ muscle TnC, as well as PV,^{102,103} show that the chemical shifts of $^{113}\text{Cd}^{2+}$ ions bound to normal EF-hand sites fall in a rather narrow range (–85 to –115 ppm), in contrast to $^{113}\text{Cd}^{2+}$ bound to the pseudo-EF-hand in CB-9 which resonates at –155 ppm. Cadmium-113 NMR has been used also in the study of the interaction of CaM with hydrophobic drugs^{79,105} and amphipathic peptides.¹⁰⁶ The latter study showed that both globular domains of CaM participate in peptide binding, in agreement with ^1H NMR studies and structure determination (see *Calmodulin*).

Overviews of ^{113}Cd NMR studies of CABPs are given in two recent reviews of metal-ion NMR.^{89,106} Another substitution probe for Ca^{2+} is yttrium, which has 100% natural abundance as the NMR-active isotope ^{89}Y . Yttrium –89 NMR studies of Y^{3+} ions bound to the two calcium sites in PV have been reported.¹⁰⁷

7 STUDIES OF ^{25}Mg , ^{23}Na , AND ^{39}K INTERACTING WITH CABPs

The biological environment of CABPs often contains high levels of Mg^{2+} , Na^{+} , and/or K^{+} . The interaction of these metal ions with CABPs, as well as their influence on the calcium binding process, is therefore of considerable importance. The quadrupolar isotopes ^{25}Mg , ^{23}Na , and ^{39}K can be observed directly by NMR, and the spectral properties and analysis are analogous to that of ^{43}Ca (cf. above and Forsén et al.). Tsai et al. used ^{25}Mg NMR in a thorough analysis of the Mg^{2+} -binding properties of the four EF-hand sites in CaM, and provide a comprehensive outline of the methodology.¹⁰⁸ Magnesium-25 NMR has also been used to assess the Mg^{2+} -binding properties of many other CABPs, for example prothrombin fragment 1,¹⁰⁹ PV,¹¹⁰ and β -casein.¹¹¹ The Na^{+} -binding properties of TnC and its tryptic fragments, in relation to calcium binding, have been studied by ^{23}Na NMR.¹¹² Combination of ^{39}K NMR, for determining the K^{+} affinity for CB-9, and 2D ^1H NMR to assess chemical shift perturbations caused by K^{+} binding, has shown that K^{+} associates weakly on the surface of this protein without causing structural changes.⁷⁷

1 INTRODUCTION

Calmodulin (CaM) was discovered as an activator of cyclic nucleotide phosphodiesterase in brain by Cheung¹ and by Kakiuchi and Yamazaki² in 1970. Since then, it has become clear that CaM is a ubiquitous intracellular calcium receptor present in eukaryotic cells and that its structure has been highly conserved during evolution.³ The amino acid and gene sequences of CaM from various species have been determined.^{4–6} Figure 1 shows the amino acid sequence of bovine brain CaM.⁴ The molecular weight of CaM is ca. 16 700. The amino terminal is acetylated and lysine-115 is trimethylated at the ϵ position. CaM consists of four repeated sequences of about 35 amino acid residues, each of which forms a helix–loop–helix Ca^{2+} -binding motif of the EF-hand type, first discovered in parvalbumin by Kretsinger and co-workers.⁷ The biophysical properties of CaM have been extensively studied (for reviews, see Cohen and Klee⁵). CaM is an acidic ($\text{pI} = 4.3$) and heat stable protein which binds four Ca^{2+} ions. The four Ca^{2+} -binding motifs can be classified into the high affinity sites III and IV in the C-terminal region ($K_d \approx 10^{-6}$ M) and the low affinity sites I and II in the N-terminal region ($K_d \approx 10^{-5}$ M).⁸

A number of enzymes and proteins have been reported to date to be stimulated by CaM.⁴ These include myosin light chain kinase (MLCK), CaM kinase II, phosphorylase kinase, calcineurin, myristoylated alanine-rich C kinase substrate (MARCKS), and many others (for reviews, see Cohen and Klee⁵ and Crivici and Ikura⁶). Thus, CaM plays a role as a multifunctional activator or regulator in various Ca^{2+} -dependent cellular processes. CaM-binding regions in many target enzymes and proteins have been mapped. These regions are generally small (14–27 amino acid residues) and rich in basic and hydrophobic residues. Most of the CaM-binding sequences identified so far appear to have a propensity for helix formation. A number of naturally occurring peptides are also known to bind CaM in a Ca^{2+} -dependent manner.⁹ These peptides include insect venom peptides such as mastoparans and melittin, and certain hormones and opioids such as ACTH, VIP, glucagon, and substance P. In addition, phenothiazines and other hydrophobic drugs including trifluoperazine (TFP), chlorpromazine, and W-7, bind CaM and inhibit the CaM-mediated activation of enzymes.¹⁰ Proteolytic fragments and synthetic peptides comprising the CaM-binding regions of target proteins, as well as the insect and hormone peptides and

Figure 1 The amino acid sequence of bovine brain calmodulin⁴ [Courtesy of C. B. Klee]

the hydrophobic drugs, have been extensively used to study the structural and biochemical properties of the interaction of CaM with targets.

The crystal structures of Ca^{2+} -loaded CaM were reported by Babu et al.¹¹ in 1985 and by Kretsinger et al.¹² in 1986. The structures have an unusual dumbbell shape [Figure 2(a)] in which the N- and C-terminal globular domains are connected by a long α -helix. The length of the molecule is about 65 Å, with each lobe having approximate dimensions of $25 \times 20 \times 20$ Å.³ Each domain possesses a hydrophobic patch, which is considered to be responsible for target binding. Similar structural features were found in the crystal structure of a homologous Ca^{2+} -binding protein, skeletal muscle troponin C¹³ (see *Calcium-Binding Proteins and Muscle Proteins*). In 1992, an NMR structure of CaM complexed with a 26-residue CaM-binding peptide derived from skeletal muscle MLCK was determined¹⁴ [Figure 2(b)]. Subsequently, a crystal structure of CaM complexed with a smooth muscle MLCK peptide was also solved at 2.4 Å. More recently, a crystal structure of CaM complexed with a CaM kinase II peptide has been reported.¹⁶

Detailed mechanisms by which CaM regulates the activity of target enzymes and proteins are still not yet fully understood even for a single case. Nevertheless, NMR spectroscopy has contributed tremendously to our understanding of the structural basis of the action of CaM in the context of interactions with

Ca^{2+} , and peptides and drugs. In the following discussion NMR studies on CaM reported during the period of 1979–93 will be summarized.

2 INTERACTIONS WITH METAL IONS AND DRUGS

The first 250- and 360-MHz ^1H NMR spectra of bovine brain CaM were reported by Seamon^{17,18} in 1979 and 1980, who demonstrated that dramatic Ca^{2+} -dependent spectral changes could be monitored by ^1H NMR. Aromatic proton resonances of Tyr-99, His-107, and Tyr-138, and a unique trimethyl group of ϵ -trimethylated Lys-115 were identified. Klevit et al.¹⁹ and Krebs and Carafoli²⁰ studied the interaction of bovine brain CaM with TFP using ^1H NMR. Shimizu et al.^{21,22}

used ^{19}F NMR to study the interactions of porcine brain and *Tetraphymena pyriformis* CaM with TFP. All these studies indicate that one CaM molecule binds two TFP molecules.

More detailed assignments for aromatic ring and methyl protons in scallop testis CaM were reported by Ikura et al.²³ in 1983. Using those resonance assignments, Ca^{2+} -induced conformational changes have been examined.²⁴ Figure 3 illustrates Ca^{2+} -induced changes in the aromatic region of the ^1H NMR spectra. The results show that many resonances C-terminal domain (Phe-99, His-107, trimethyl Lys-115, and Tyr-138) are shifted in an early stage of Ca^{2+} titration (0–2 mol Ca^{2+} per mol of CaM), thus concluding that the C-terminal domain contains the high affinity sites for Ca^{2+} . Forsén and co-workers independently reached the same conclusion from ^{43}Ca and ^{113}Cd NMR studies^{25,26} using two tryptic fragments

Figure 2 Ribbon diagram representations of (a) Ca^{2+} -CaM¹¹ and (b) the Ca^{2+} -CaM-M13 complex¹⁴ as generated by the program ribbons. The CaM N-terminal domain is shown in blue and the C-terminal domain in red. In Figure 2(b), the structure is viewed parallel to the M13 peptide helix axis

of CaM (TR₁C, fragment 1–75; TR₂C, fragment 78–148). These half-fragments were found to be extremely useful for NMR studies of CaM. In 1984, ¹H NMR studies on the half-fragments were reported by three groups^{27–30} almost at the same time. Two uniquely low-frequency shifted ring proton resonances at 6.46 and 6.50 ppm of apo-CaM were assigned to phenylalanines in the N-terminal domain. All these studies provided further evidence for the order of Ca^{2+} binding to four sites in CaM. Together with ⁴³Ca and ¹¹³Cd NMR^{25,26} and other biophysical studies,^{4,5,8} it became clear that the two tryptic half-fragments retain the conformations which they assume in whole CaM. The property was shown for both the Ca^{2+} -free and Ca^{2+} -bound forms.

Because of the complexity of the ¹H NMR spectra of whole CaM, several groups used the tryptic half-fragments to elucidate the structural details of CaM. In 1984, Aulabaugh et al.³¹ applied 2D ¹H NMR at 600 MHz to fragment TR₂C in the absence of Ca^{2+} and obtained assignments for many side-chain proton resonances to particular amino acid types. In 1985, Ikura et al.³² applied 2D ¹H NMR techniques to the TR₂C fragment both in the presence and the absence of Ca^{2+} , and obtained about 30% backbone and side-chain proton assignments in each state using the sequential assignment

procedure proposed by Wüthrich and co-workers (see *Biological Macromolecules: Structure Determination in Solution and Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). Extremely high-frequency shifted amide proton resonances (10.0–11.0 ppm) were assigned to the glycine residues at the fifth position of the Ca^{2+} -binding loops. These uniquely shifted glycine amide resonances were further characterized using both TR₁C and TR₂C fragments.³³ Such large shifts of the amide protons of this conserved glycine residues in EF-hand Ca^{2+} -binding loops were also found in troponin C³⁴ and calbindin³⁵ (see *Calcium-Binding Proteins*), suggesting that this feature is universal among the members of the EF-hand superfamily. Hoffman and Klevit³⁶ reported 2D ¹H NMR analysis of the Ca^{2+} -free TR₁C fragment in the absence of Ca^{2+} , indicating hydrophobic contacts between Phe-16 and Val-35 which are absent in the Ca^{2+} -bound form of the crystal structure.^{11,12} More recently, Finn et al.³⁷ obtained the complete backbone ¹H resonance assignments of the Ca^{2+} -free TRC fragment, indicating that the Ca^{2+} -free state retains the helix-loop-helix secondary structure similar to that observed in the Ca^{2+} -bound form.^{11,12,38}

Figure 3 The aromatic region of the 400 MHz ^1H NMR spectra of scallop testis calmodulin at various Ca^{2+} concentrations. (Reproduced by permission of the American Chemical Society from Ikura et al.²⁴)

Several different NMR techniques were used to study the kinetics of Ca^{2+} binding to CaM and its fragments. Calcium-43 and ^{113}Cd NMR studies^{25,26} indicate that the resonances from metal ions bound to sites III and IV show much slower exchange on the NMR timescale than those from metal ions bound to sites I and II. ^1H NMR saturation transfer and spectral simulation methods were employed to obtain the exchange rate constants and activation parameters between Ca^{2+} -free and Ca^{2+} -bound forms of two half-fragments.³⁹ Two distinct rate constants of $3\text{--}10\text{ s}^{-1}$ and $300\text{--}500\text{ s}^{-1}$ were found at 22°C for the C-terminal and the N-terminal fragments, respectively. All these results confirm the identification of sites III and IV as being the high affinity sites.

Starovasnik et al.⁴⁰ studied the Ca^{2+} binding and structural properties of CaM from the yeast *Saccharomyces cerevisiae* using flow dialysis and ^1H NMR. The amino acid sequence of yeast CaM is 60% identical to that of vertebrate CaM, whereas all known vertebrate CaM sequences are totally identical. The results indicate that, unlike vertebrate CaM, yeast CaM binds only three Ca^{2+} ions and that all three sites exhibit slow-exchange behavior upon Ca^{2+} binding. Thermal denaturation properties of yeast CaM as well as of its half-fragments were also studied. Starovasnik et al.⁴¹ studied a series of four site-directed mutants using the same techniques, demonstrating interactions between the Ca^{2+} -binding sites in CaM.

Vogel and co-workers have extensively studied lysine residues in CaM using ^1H and ^{13}C NMR. The pK_a values of *N*-dimethylated lysine residues were obtained both in apo and Ca^{2+} -bound forms, as well as in a complex with a 22-residue peptide comprising the CaM-binding region of skeletal muscle

MLCK.^{42,43} Zhang et al.⁴⁴ applied ^{14}N NMR to ϵ -trimethyl Lys-115 in both vertebrate and yeast CaMs. The ϵ -trimethyl group of this posttranslated lysine gives rise to a sharp ^{14}N NMR resonance because of its unique tetrahedral symmetry. Selenium-77 NMR was used to study the microenvironments of the nine methionine residues in CaM, all of which were biosynthetically substituted with selenomethionine.⁴⁵

3 CALCIUM-CALMODULIN COMPLEX

During the period 1989–93, CaM was extensively used by Bax's group at the NIH to develop multidimensional heteronuclear MR methods (see *Multidimensional Spectroscopy: Concepts, and Three- and Four-Dimensional Heteronuclear Magnetic Resonance*). This methodology requires isotope enrichment of proteins with ^{15}N and ^{13}C . Uniformly ^{15}N - and ^{13}C -labeled CaM was obtained using an *E. coli* expression system.⁴⁶ Figure 4 shows a ^1H – ^{15}N heteronuclear single quantum coherence (HSQC) spectrum of Ca^{2+} -loaded recombinant CaM labeled uniformly with ^{15}N , illustrating that a high-quality ^1H – ^{15}N shift correlation spectrum can be obtained at 1 mM protein concentration. Ikura et al.^{38,47} reported complete backbone and side-chain ^1H , ^{13}C , and ^{15}N assignments of Ca^{2+} -loaded recombinant *Drosophila* CaM using a series of triple- and double-resonance 3D and 4D experiments. The secondary structure in solution was then characterized using NOE, $^3J_{\text{NH}\alpha}$ coupling constants, and ^{13}C chemical shift data.³⁸ These results confirm the crystal structure^{11,12} in that both the N- and C-terminal globular domains assume a pair of the EF-hand type helix–loop–helix motifs. However, the central helix portion (residues 65–92), found in the crystal structure, appears to contain a nonhelical region at residues 78–81 in solution. Nitrogen-15 relaxation studies reported by Barbato et al.⁴⁸ further indicate that this nonhelical portion has considerable flexibility, consistent with other studies using solution techniques such as small angle X-ray or neutron scattering.⁴⁹ The ^{15}N relaxation studies⁴⁸ (see *Protein Dynamics from NMR Relaxation*) provide additional interesting insights into the structure and dynamics of Ca^{2+} –CaM. The rotational correlation times obtained for the N- and C-terminal domain (7.1 ns and 6.3 ns, respectively) do not reflect the overall motion of a 16.7 kDa protein, but rather correspond to that of a smaller protein (ca. 12 kDa). Further, the correlation times for the individual amide bond vectors vary to a much lesser degree than predicted by hydrodynamic calculations for rigid dumb-bell models. These results indicate that the two domains move independently in solution.

4 CALCIUM-CALMODULIN-PEPTIDE TERNARY COMPLEXES

In 1985, Klevit et al.⁵⁰ using ^1H NMR studied the interaction of CaM with a 26-residue synthetic peptide (known as M13) comprising the CaM-binding domain of skeletal muscle myosin light chain kinase. These data indicate that both the N- and C-terminal domains must participate in the interaction with the M13 peptide. The ^{113}Cd NMR studies of mastoparan binding to Cd_4CaM have shown that both the N- and C-terminal domains undergo conformational

Figure 4 The 500 MHz ^1H - ^{15}N HSQC shift correlation spectrum of *Xenopus laevis* calmodulin. The spectrum was recorded using a pulse sequence combined with the pulse field gradient technique described by Kay et al.⁶⁶ The full backbone amide assignment of *Xenopus* calmodulin is available from the author

changes upon binding of the peptide (see **Calcium-Binding Proteins**). Seeholzer et al.⁵¹ also used ¹H NMR to study the interaction of melittin with [¹H]- and [²H]-CaM, suggesting that melittin assumes an α -helical conformation upon binding CaM, consistent with earlier conclusions based on circular dichroism spectra. Yazawa et al.,⁵² using the ¹H NMR signal of His-107, showed that in the presence of M13 the Ca²⁺-dependent conformational change becomes completely cooperative between the N- and C-terminal domains. Ikura et al.⁵³ studied the Cd²⁺ dependence of the interactions of CaM with M13 and mastoparan using ¹¹³Cd NMR, supporting the notion of the higher cooperativity of metal binding in the presence of these peptides. Ohki et al.^{54,55} studied the interaction of mastoparan with CaM under various solution conditions using ¹H NMR. It was shown that the N-terminal domain may interact with a second mastoparan molecule with a lower affinity, and that Mg²⁺ reduces the cooperative Ca²⁺ binding to CaM in the presence of mastoparan.

In 1991, Ikura et al.⁵⁶ completed ¹H, ¹³C, and ¹⁵N backbone assignments of Ca²⁺-CaM complexed with M13 by using multidimensional heteronuclear MR methods. Proton assignments of M13 in the complex were also obtained using ¹⁵N/¹³C-filtered techniques⁵⁷ (see **Half-Filter Experiments: Proton-Carbon-13**). Based on these assignments, the three-dimensional NMR structure of the Ca²⁺-CaM-M13 ternary complex was determined.¹⁴ Figure 2(b) shows a schematic ribbon model of the restrained minimized mean structure. A striking difference in conformation can be seen as compared with the crystal structure of Ca²⁺-CaM¹¹ [Figure 2(a)]. The N- and C-terminal domains of CaM (residues 6–73 and 83–146) remain essentially unchanged upon complexation. The long central helix, (residues 65–93), however, which connects the two domains in the crystal structure of Ca²⁺-CaM [Figure 4(a)], is disrupted into two helices connected by a long flexible loop (residues 74–82), thereby enabling the two domains to clamp residues 3–21 of the bound peptide which adopt a helical conformation. Key residues of the peptide are Trp-4 and Phe-17, which serve to anchor the N- and C-terminal halves of the peptide to the C- and N-terminal domains of CaM, respectively. This characteristic structure of Ca²⁺-CaM complexed with the M13 peptide was confirmed by a crystallographic study on Ca²⁺-CaM complexed with a similar peptide derived from smooth muscle MLCK.¹⁵ Based on the knowledge of the structural features of these Ca²⁺-CaM-peptide complexes, Prumb et al.⁵⁸ produced a hybrid CaM-peptide molecule and characterized the structural and Ca²⁺-binding properties using ¹H–¹⁵N HSQC and flow dialysis experiments.

Roth et al.^{59,60} revealed the secondary structure of a 19-residue smooth muscle MLCK peptide and CaM in their complex using heteronuclear multidimensional NMR techniques. Most of the backbone amide nitrogen nuclei in the MLCK peptide were labeled with ¹⁵N, which allowed the characterization of the α -helix structure of the peptide. Precheur et al.⁶¹ also used a similar labeling technique on a 17-residue model peptide proposed by DeGrado et al.,⁶² and showed a stable α -helical structure in the N-terminal 11 residues of the complex. Zhang et al.,^{63,64} using 2D ¹H NMR, studied three synthetic CaM binding peptides which are derived from skeletal muscle MLCK, rat cerebellar nitric oxide synthase, and smooth muscle caldesmon. The MLCK⁶³ and caldesmon⁶⁴ peptides were found to assume an α -helical conformation in an aqueous trifluoroethanol mixture

(75%/25%) The nitric oxide synthase peptide⁶⁶ also adopts an α -helical structure in aqueous solution at pH 5.5 and 5 °C.

In summary, CaM has provided an excellent example of the power of the high-resolution multinuclear magnetic resonance approach. Various NMR studies have provided valuable information on the structural and physical properties of CaM as a Ca²⁺-sensitive molecular switch in cells. Yet, further studies have to come in order to elucidate secrets involved in multitarget recognition of this amazing molecule.

1 INTRODUCTION

The expansion of glycobiology into the realm of the structure–function relationships of carbohydrates is strongly dependent upon advances in technology. Unquestionably, nuclear magnetic resonance (NMR) spectroscopy has made the most significant impact on structural studies of oligosaccharides and glycoconjugates. While researchers in the past (1960–84) concerned themselves in the first place with the study of primary carbohydrate structures, NMR spectroscopy has recently (1985–94) reached a level of sophistication which allows the conformational analysis of oligosaccharides, glycopeptides, and glycolipids in solution. This article briefly summarizes the early days of carbohydrate NMR, reviews the application of current NMR spectroscopic techniques to the structural and conformational characterization of oligosaccharides from glycoproteins and glycolipids, and ends with a discussion of some questions about carbohydrate structure, dynamics, and function that can be addressed by NMR in the near future.

2 CARBOHYDRATES AND GLYCOCONJUGATES: STRUCTURE AND FUNCTION

The carbohydrate moieties of glycoconjugates, i.e., glycoproteins and glycolipids, generally have complex structures featuring highly varied chemical functionalities. These oligosaccharide chains, varying in size from two to 20 or more residues, are composed of neutral monosaccharides such as d-mannose (Man) and d-galactose (Gal), amino sugars such as *N*-acetyl-d-glucosamine (GlcNAc) and *N*-acetyl-d-galactosamine (GalNAc), the C-6-deoxy sugar l-fucose (Fuc), and the nine-carbon-atom acidic sugars of the sialic acid family of which *N*-acetylneuraminic acid (Neu5Ac) is the most commonly found representative (for structures, see Figure 1). In glycoproteins, these oligosaccharide chains are covalently

attached to the side chains of specific amino acids such as Asn, Ser, and Thr. Glycoproteins are anchored to the outer surface of the cell's plasma membrane by either a transmembrane peptide fragment or by a phosphatidyl-inositol anchoring lipid. Complex carbohydrate chains similar to those of glycoproteins may also be found attached to lipids similarly inserted in the plasma membrane where they present the hydrophilic carbohydrate chain to the extracellular environment (Figure 1).

Because of their structural diversity, glycoconjugate oligosaccharides are potentially rich sources of biological information. Although the precise function of the carbohydrate chains of glycoproteins and glycolipids is not fully understood, it has been proposed that they are informational macromolecules with signals encoded in their structure that are crucial to the biological functions of the cells carrying them.¹ As this information apparently relates to intercellular communication and control of cellular growth and differentiation, it is possible that complex carbohydrates play an important role in such important processes as developmental biology and tumor metastasis. Areas of focus in current glycobiology research include the importance of oligosaccharides to immune mechanisms, the association of certain structural changes with diseases such as malignant cancer growth and rheumatoid arthritis, and the potential for the development of novel therapeutic strategies [recombinant glycoproteins such as erythropoietin and tissue plasminogen activator are already in widespread clinical use for the treatment of anemia and myocardial infarction, respectively, while the glycolipid 'ganglioside GM1' (Figure 1) is administered to alleviate the symptoms of cholera].

From a structure–function point of view, the 20th century has come full circle: Landsteiner's discovery, around 1900, of the ABH blood group antigens inspired structural studies that culminated in the identification of the antigens as tri- and tetrasaccharide epitopes at the nonreducing termini of the glycoprotein and glycolipid carbohydrate chains found on the cell surface of erythrocytes and many other mammalian tissues (Figure 1). Landsteiner's pioneering work sparked investigations into the involvement of carbohydrates in immune protection and in graft versus host reactions in blood transfusions and other organ transplants. The presence of sialic acid on erythrocyte surfaces proved to be a necessary requirement for their infection by the influenza virus. Malignant tumor cells were found to exhibit certain tumor-associated antigens (TAA), carbohydrate sequences not found on membrane glycoproteins and glycolipids of normal cells. TAA-like epitopes were discovered on cell surfaces in the early stages of embryonic development (hence, they are known as onco-fetal antigens).^{2–4} Around 1990, the discovery and identification of sialylated Lewis blood group carbohydrates (sLe^a and sLe^x, Figure 1) as ligands for selectins (cell adhesion molecules)^{5,6} added the latest exciting chapter to the involvement of oligosaccharides in an important biological process, in this case endothelial leukocyte adhesion being the key to inflammation.

From the beginning it was understood that an insight into the biological and physicochemical functions of complex carbohydrates at the molecular level would require a precise knowledge of the primary and secondary structures of these often highly branched polymers with their intriguing blend of segmental rigidity and flexibility. The complete structural characterization of complex carbohydrates involves

Figure 1 (a) Schematic representation of a cell's plasma membrane with an emphasis on the glycoprotein and glycolipid carbohydrate chains, the cell's communication organelles. (b) Primary structures of some commonly found glycoprotein and glycolipid carbohydrate chains. Represented from top to bottom: a diantennary *N*-type glycoprotein oligosaccharide, an *O*-type glycoprotein tetrasaccharide, and the monosialo and disialo gangliosides G_{M1} and G_{D1a} (Asn = l-asparagine; Ser = l-serine; Cer = ceramide, the generic name for an *N*-acylated sphingosine). (c) Structures of typical constituent monosaccharides of glycoprotein and glycolipid oligosaccharide chains (Man, Gal, GlcNAc, GalNAc, Fuc, and Neu5Ac, drawn in the α -configuration of their thermodynamically most stable pyranose ring forms). determining (i) the type, number, and primary sequence of the constituting glycosyl residues, including the occurrence of branch points and the location of appended noncarbohydrate groups and (ii) their three-dimensional (3D) conformation(s) and dynamics in solution. Although determining the complete structure of a carbohydrate usually requires the application of a combination of chemical, enzymatic, and spectrometric methods,^{7,8} NMR spectroscopy has emerged as the single most powerful technique for the accomplishment of this task. The nuclei of predominant interest in NMR studies of carbohydrates are ^1H and ^{13}C . The natural allocation of hydrogen and carbon atoms in carbohydrate molecules lends itself to the revelation of their complete primary structure through ^1H and ^{13}C NMR analysis. Whereas the

primary structural characterization of carbohydrates relies on a combination of techniques, only one of which is NMR spectroscopy, solution conformation analysis is almost entirely the domain of NMR spectroscopy. X-ray structures of glycoconjugates are not commonly available (and if they are, carbohydrates are usually not well-defined), and molecular modeling of carbohydrates, although a hotly contested area of research, is still in its infancy and, therefore, of little help to the experimentalist to date.

The purpose of this review is to put NMR of carbohydrates and glycoconjugates in its historical perspective; not surprisingly, a chronological account shows a remarkable parallel with primary and three-dimensional structure analysis. It should be noted that NMR of carbohydrates covers a much

broader area than solution-state ^1H and ^{13}C NMR of monosaccharides, oligosaccharides, and glycoconjugates. Polysaccharides are the topic of the article by Bush (*Polysaccharides and Complex Oligosaccharides*), and ^2H NMR of glycolipids is covered in Jarrell's article (*Glycolipids*). Here we will cover neither the application of solid state NMR to carbohydrates nor touch upon ^{31}P NMR of sugar phosphates, ^{15}N NMR of amino sugars, ^{17}O NMR of carbohydrates, and NMR of X-nuclei (^{11}B , ^{119}Sn , etc.) in carbohydrate adducts (see, for example, Bush⁹). We will further limit the discussion in this article largely to pyranose ring systems. For the discussion of furanose rings and their flexibility, the reader is referred to articles by Altona (*Vicinal Coupling Constants and Conformation of Biomolecules*), Hilbers (*Nucleic Acids: Spectra, Structures, and Dynamics*), and others covering NMR of nucleic acids. Furthermore, the molecules (peptides/proteins, lipids) that serve as appended groups of carbohydrates in glycoconjugates are discussed elsewhere throughout this Encyclopedia.

3 THE PAST: PRIMARY STRUCTURE

The initial discovery of the potential value of NMR spectroscopy for carbohydrate structural and conformational analysis is described by Lemieux in his book entitled 'Explorations with Sugars: How Sweet It Was'.¹⁰ We quote:

In spite of the difficulties and shortcomings of the NMR technique [in 1955], it became evident that acetylated sugars, because of large differences in chemical shifts, were very interesting substances with which to explore the possible use of ^1H NMR spectroscopy in organic chemistry. It soon became apparent that an equatorially oriented hydrogen generally gave rise to a signal at a lower field compared with that of a chemically similar but axial hydrogen.¹¹ This discovery was very encouraging. However, the big excitement came when [...] significant improvements in resolution were made. Examination of the spectra of [...] cyclohexanol acetates firmly established that the spin-spin coupling constants for vicinal hydrogens in antiperiplanar orientation were two to three times larger than those for vicinal hydrogens in a synclinal relationship.¹² [...] The discovery provided the long-sought definitive basis for the assessment of the preferred conformations of the sugar acetates in solution. [...] The spectra of *trans,trans*- and *cis,trans*-di-*O*-methylcyclohexanol acetate, shown in Figure 2, represent the first application of NMR for the establishment of the relative configurations of chiral centers in organic compounds. Thus, the experimental foundation was laid for the Karplus relationship¹³ between the vicinal coupling constant and the torsion angle and for the use of the time-averaged coupling constants to estimate conformer populations.

The stereochemistry of a particular monosaccharide provides its signature in the ^1H NMR spectrum; the ^1H signals of most monosaccharides can readily be assigned to the appropriate (aliphatic) protons by making use of the observed chemical shifts and splitting patterns. Thus, the foundation for the identification of carbohydrates by ^1H NMR spectroscopy had been laid.

Section 3.1 below elaborates on the empirical rules that emerged from the inspection of ^1H and ^{13}C NMR spectra of monosaccharides and simple oligosaccharides of known primary structure. Sections 3.2 and 3.3 below summarize 1D ^1H NMR spectroscopy as a fingerprinting method for

Figure 2 The first application of ^1H NMR spectroscopy, at 40 MHz, for the determination of stereochemical configuration (adapted from Lemieux et al.;¹⁴ spectra reproduced with permission from the American Chemical Society). For the *cis,trans* isomer, $^3J(\text{H-1},\text{H-2}) = 3\text{ Hz}$ and $^3J(\text{H-2},\text{H-3}) = 7\text{ Hz}$ (traces a and b); for the *trans,trans* isomer, $^3J(\text{H-1},\text{H-2}) = ^3J(\text{H-2},\text{H-3}) = 7\text{ Hz}$ (traces c and d)

the characterization of the primary structure of glycoprotein and glycolipid oligosaccharide chains, respectively, and the usefulness of an empirical concept that emerged during the 1980s for the interpretation of the ^1H NMR spectrum of a glycoprotein or glycolipid carbohydrate in terms of its primary structure is outlined. Ongoing efforts aimed at computer-assisted carbohydrate NMR spectral 'interpretation' are mentioned as well. Finally, Section 3.4 takes the concepts developed in previous sections to the level of de novo primary structural elucidation of glycoconjugate carbohydrates by 1D and 2D ^1H and ^{13}C NMR spectroscopy.

3.1 Monosaccharides and Simple Oligosaccharides

As their generic name implies, carbohydrate molecules contain numerous carbon and hydrogen nuclei. It follows that the magnetically active nuclei in carbohydrates that are of practical interest to NMR spectroscopists are those of ^1H

and ^{13}C atoms. For example, each hexosyl residue [such as the galactosyl residue in Figure 3(a)] has six carbon atoms, seven hydrogens that are involved in CH linkages, and four hydrogens in OH groups. Each of these nuclei in a glycosyl residue has its own characteristic environment and, thus, its own chemical shift. For primary structural characterization of a carbohydrate by ^1H NMR spectroscopy, the observation of the aliphatic protons suffices. Observation of hydrogens in OH groups would unnecessarily complicate spectra aimed at primary structural characterization. Therefore, the carbohydrate sample is typically dissolved in D_2O (no chemical derivatization is necessary), effectively removing any OH signals from the spectrum. Chemical shifts are referenced to the methyl signal of DSS (sodium 4,4-dimethyl-4-silapentane-1-sulfonate). The ^1H NMR spectrum of an oligosaccharide is essentially a superposition of the spectra of the individual glycosyl residues which are slightly modified because of their linkages to each other. For example, the ^1H NMR spectra of typical glycoprotein Ser-linked tri- and tetrasaccharides are shown in Figures 3(b) and 3(c).¹⁵ The subspectrum of the β -galactosyl residue is recognizable in the spectra of both the linear trisaccharide and the branched tetrasaccharide. Furthermore, Figure 3(c) clearly illustrates the difference in the NMR appearance of an $\alpha(2\rightarrow3)$ - versus an $\alpha(2\rightarrow6)$ -linked sialic acid.

The following empirical 'rules' have emerged to guide the interpretation of ^1H NMR spectra of simple carbohydrates:

1. The nonanomeric ring-skeleton protons in a glycosyl residue have very similar electron densities and, thus, chemical shifts; all of their signals appear between 3 and 4 ppm (Figures 3 and 4). In the spectrum of an oligosaccharide, the signals of the nonanomeric protons partially overlap; they constitute a broad envelope of signals in the middle of the spectrum having little fine structure and, therefore, almost no readily accessible structural information. However, anomeric protons (H-1) show signals at significantly higher chemical shifts due to their neighboring glycosidic and ring oxygens. Anomeric proton doublets are typically found between δ 4.3–5.6 ppm.

2. A proton in an equatorial position at a certain carbon atom in a pyranose ring has a chemical shift ~ 0.5 ppm higher than the corresponding axial proton attached to the same carbon. Therefore, for d-residues involved in α -glycosidic linkages (H-1 equatorial), $\delta(\text{H-1}) \sim 4.9\text{--}5.6$ ppm, while for β -anomeric linkages (H-1 axial), $\delta(\text{H-1}) \sim 4.3\text{--}4.7$ ppm. For carbohydrates in D_2O at ambient temperature, these positions correspond to the near left and right of the HDO signal (at $\delta \sim 4.80$), respectively. Further illustrating this rule, the equatorial Man H-2 signals are typically found ~ 0.5 ppm further to the left than the axial GlcNAc or Gal H-2 signals (Figure 4). Also, Gal H-4 protons resonate ~ 0.5 ppm further to the left than GlcNAc H-4 protons (compare Figure 3).

3. Each anomeric proton, by virtue of its $^3J(\text{H,H})$ scalar coupling to H-2, resonates as a doublet. The magnitude of the coupling constant reflects the relative orientation of neighboring protons. The coupling constant $^3J(\text{H-1,H-2})$ for two neighboring protons (H-1 and H-2, separated from each other by three covalent bonds) that are both in axial orientation is 7–8 Hz (i.e., relatively large), while coupling constants $^3J(\text{H-1,H-2})$ between two neighboring protons, one of which is axial and the other equatorial, or between two equatorial protons, are 3–4 Hz (relatively small). Thus, the anomeric configuration of a glycosyl residue can be inferred both from

Figure 3 (a) The computer-simulated ^1H NMR spectrum of a β -linked galactopyranosyl residue in D_2O . (b) The 600 MHz ^1H NMR spectrum (D_2O , $\text{pD} = 6$, 23°C) of a linear O -type trisaccharide-alditol ($70\ \mu\text{g}$) obtained from a glycoprotein via reductive alkalineolysis.¹⁵ (c) The 600 MHz ^1H NMR spectrum (D_2O , $\text{pD} = 6$, 23°C) of an O -type tetrasaccharide-alditol ($75\ \mu\text{g}$) released from a glycoprotein via reductive alkalineolysis.¹⁵ Superscripts in NeuAc³ and NeuAc⁶ refer to the position of the linkage in which these residues are involved

Figure 4 (a) The 500 MHz ^1H NMR spectrum (D_2O , $\text{pD} = 6$, 21°C) of a typical diantennary N -type oligosaccharide side chain of a glycoprotein (250 μg , examined as oligosaccharide-alditol, obtained by N -glycanase digestion of the glycoprotein and subsequent chemical reduction). The residual HOD signal was suppressed by low-power presaturation. (b) Structural-reporter-group regions of spectrum (a). The numbers in the spectra refer to the corresponding glycosyl residues in the structure

the chemical shift and the coupling constant of its anomeric-proton signal in the ^1H NMR spectrum.

4. When a glycosyl residue has either an additional glycosyl residue or a noncarbohydrate group attached at a certain carbon position, the signal of the proton attached to this carbon tends to shift ~ 0.2 – 0.5 ppm to the left in the spectrum. Therefore, signals of nonanomeric protons that are attached to linkage sites usually appear just outside the envelope resonance of skeleton protons ($3.9 < \delta < 4.4$) (Figure 4); they become individually observable ‘structural-reporter’ signals (Section 3.2). Thus, if the nonanomeric proton signals that emerge in the region between δ 3.9 and 4.4 ppm can be assigned, linkage positions can be deduced from a ^1H NMR spectrum.

These rules are the result of the extrapolation and rationalization of numerous NMR data obtained on mono- and disaccharides of known primary structure. Noteworthy review articles on general applications of NMR to carbohydrates, developing *inter alia* the above concepts, have appeared^{2,16,17}

including one recently.¹⁸ Additionally, the scientific literature includes extensive ^1H databases of chemical shifts for mono- and small oligosaccharides.^{19,20}

The first reports on ^{13}C NMR spectroscopy of carbohydrates appeared in the late 1960s.^{21,22} It was found that the ring ^{13}C methine signals of pyranosyl residues are typically observed between 65 and 110 ppm downfield from DSS. Anomeric carbons usually resonate between 90 and 110 ppm. The magnitude of the one-bond $^1J(\text{C}-1, \text{H}-1)$ coupling for the anomeric carbon atoms reflects the configuration at the anomeric center. As a rule of thumb, $^1J(\text{C}-1, \text{H}-1) \sim 170$ Hz indicates the α -anomeric configuration, whereas $^1J(\text{C}-1, \text{H}-1) \sim 160$ Hz indicates the β -anomeric configuration. The exocyclic methylene signals of monosaccharides (in CH_2OH groups) are observed at ~ 60 – 70 ppm [unless the glycosyl residue is involved in a (1→6) linkage]. Extensive ^{13}C databases for mono- and simple oligosaccharides are found in the literature.^{23–28} Glycosylation shifts ($\Delta\delta \sim 10$ ppm for ^{13}C at the site of substitution, $\Delta\delta = 1$ to -2 ppm for the adjacent ^{13}C atoms) are more reproducible in ^{13}C NMR than in ^1H NMR of carbohydrates. Computer-assisted interpretation of NMR spectra of carbohydrates in terms of primary sequence based solely on ^{13}C chemical shifts^{29–31} preceded that of ^1H NMR spectra.^{32–34}

3.2 Complex Oligosaccharides Related to Glycoproteins

The carbohydrate side chains of glycoproteins are amenable to high-resolution ^1H NMR spectroscopy either as glycopeptides or as free oligosaccharides. These can be obtained from the glycoprotein by enzymatic or chemical procedures.^{7,8} A typical example of a ^1H NMR spectrum of a glycoprotein-derived N -type oligosaccharide is shown in Figure 4(a). In the early 1970s, when the complete interpretation of ^1H NMR spectra of carbohydrates of this size seemed impossible, the spectrum of an oligosaccharide was regarded by the glycobiologist primarily as a fingerprint, a readily obtainable ‘identity card’ of a carbohydrate. A mere comparison of the ^1H NMR spectra of compounds (without detailed interpretation) was used to demonstrate whether they were identical and/or pure substances. Thus, at first, a 1D ^1H NMR study appeared valuable for the primary structure determination of glycoprotein carbohydrates only if the oligosaccharide had been characterized previously by ^1H NMR in conjunction with chemical and other spectrometric methods.

However, in the late 1970s the first successful attempts were made to interpret the ^1H NMR spectra of glycoprotein oligosaccharides, even when the spectra did not match exactly any of the spectra in existing databases. Using the *structural-reporter-group concept*,^{15,35,36} the spectra were interpreted in terms of (partial elements of) carbohydrate primary structure, including anomeric configurations and positions of glycosidic linkages. The crux of this concept is that it appeared sufficient to inspect only certain regions in the spectrum [see Figure 4(b)] in order to ascertain the primary structure of the glycoprotein carbohydrate from its NMR spectrum. Perceived by some in the field as ‘mystical’ or ‘voodoo NMR’, the structural-reporter-group concept is merely an extrapolation of the empirical rules listed in Section 3.1 to larger oligosaccharides. The concept ignores the crowded region in the center of the spectrum (between 3–4 ppm, see

Figure 4); only the positions and patterns of those signals that are more or less individually observable are examined. Particularly useful structural-reporter groups are (i) the anomeric (H-1) protons, (ii) the protons attached to the carbon atoms in the direct vicinity of a linkage position, (iii) the protons attached to deoxy carbon atoms and (iv) methyl protons, e.g., in *N*-acetyl groups. The structural-reporter-group regions of the spectrum in Figure 4(a) are expanded in Figure 4(b). For the interpretation of a ^1H NMR spectrum such as depicted in Figure 4, structural-reporter-group signals are cataloged by chemical shift and coupling constants; these values are then compared with literature data on similar oligosaccharides and/or glycopeptides. A highly refined set of empirical rules was developed to rationalize the effects of structural elongations, as typically found in glycoprotein oligosaccharides, on structural-reporter-group chemical shifts. For example, the structural-reporter-group concept developed rules to identify the degree of branching as well as the type of linkage and branch location of sialic acid and fucosyl residues.^{15,35,36} Several glycoprotein carbohydrate structural-reporter-group ^1H chemical shift databases are currently available for *N*-type glycopeptides and oligosaccharides^{36–38} and *O*-type oligosaccharide-alditols³⁹ in D_2O ; other noteworthy databases are also available.^{40–43} The structural-reporter-group approach continues to enjoy considerable popularity as a method for the primary structural characterization of glycoprotein and glycolipid (for gangliosides, see Section 3.3) carbohydrates by NMR spectroscopy.

An important advantage of NMR spectroscopy over other techniques used for structural analysis of carbohydrates is its nondestructive nature. Oligosaccharide and glycopeptide samples, after NMR analysis, can be recovered unimpaired and used for other analyses, biological activity tests, etc. Glycoprotein oligosaccharides with 15–20 constituent glycosyl residues have been successfully characterized by 500 MHz one-dimensional (1D) ^1H NMR spectroscopy. Also, mixtures of components with closely related structures have been analyzed successfully. The most important limitation of NMR spectroscopy lies in its relatively low level of sensitivity. At least 10 nmol of pure carbohydrate is required to record an NMR spectrum and, even at 600 MHz, heterogeneity occurring in low abundance in the sample may escape attention. NMR spectroscopy, by its very nature, may also fail to detect the presence of nonmagnetically active nuclei, e.g. the occurrence of sulfate esters, in the carbohydrate.

Until now, the most laborious part of the NMR structural analysis of carbohydrates has been spectral interpretation. Partial or even complete primary structure determination is possible from the structural-reporter-group regions of a 1D ^1H NMR spectrum only if structurally closely related compounds have been previously characterized by ^1H NMR spectroscopy. The multitude of extremely refined rules resulting from the structural-reporter-group inspection of spectra makes interpretation of spectra of novel compounds a tedious effort. Even the basically simple process of retrieving previously recorded spectra and comparing them with a newly recorded spectrum becomes a considerable task, given the exponential growth of the amount of ^1H NMR data collected on glycoprotein and glycolipid oligosaccharides from 1980 to 1994. Assistance from computers to facilitate this aspect of the method is being sought along two different lines. The use

of a computer search algorithm to compare a list of structural-reporter-group chemical shifts with those in a database appears rather straightforward. Indeed, several such computer programs have been written to assist the interpretation of glycoprotein oligosaccharide ^1H NMR spectra.^{33,34,44} A more elegant and much faster method involves the use of the entire spectrum (including the 3–4 ppm envelope region with its high information density) for pattern recognition by artificial intelligence techniques. The NMR spectrum, already available in digital format, need not be reduced to a list of chemical shifts, as is commonly done for human interpretation. Artificial neural networks (ANN) have been successfully applied for pattern recognition of NMR spectra.^{45,46} Recently, this work has been extended to include the 500 MHz ^1H NMR spectra of glycoprotein carbohydrates.⁴⁷ In the foreseeable future, NMR spectral databases will be linked to the complex carbohydrate structure database (CCSD),⁴⁸ and the neural network search algorithms will be incorporated into CarbBank. This approach will not only render much of the previously necessary laborious supporting structural analysis work superfluous for oligosaccharides already in the database, it will also allow the interpretation of spectra by the rules resulting from the structural-reporter-group concept, thus ‘automating’ empirical NMR spectral interpretation.

An unexpected but welcome development in the application of the ANN technology for the analysis of ^1H NMR spectra lies in the potential increase in sensitivity of the method by two or three orders of magnitude. For a spectrum of a given oligosaccharide with fairly good signal-to-noise ratio (S/N) already in the database (i.e., when a neural network has been trained to recognize this spectrum in terms of the associated carbohydrate structure), the oligosaccharide can be recognized again from its ^1H NMR spectrum with a 100 to 1000-fold less S/N than the original spectrum (such as would be obtainable for subnanomole amounts of carbohydrate).⁴⁷ In the very near future, the ANN technology will make NMR competitive in terms of sensitivity with any other technique in the primary structural determination of carbohydrates related to glycoproteins and glycolipids.

In principle, ^{13}C NMR spectra can also be used for the fingerprinting of glycoprotein carbohydrates.⁴⁹ The ^{13}C spectra, recorded under ^1H decoupling conditions, consist exclusively of singlets. Further favored by the large chemical shift dispersion ($\Delta\delta \sim 100$ ppm), ^{13}C NMR spectra [even for intact glycoproteins (Section 5.1)] are often characterized by high resolution. Attempts were made to develop ^{13}C chemical shift databases for glycoprotein carbohydrate chains,⁵⁰ and to derive rules for the interpretation of spectra of novel compounds based on those of observed larger or smaller related structures. However, these efforts met with little success because of the higher demands on amounts of material needed for recording spectra and the much greater ease with which the same goal of primary structure characterization was achievable by ^1H NMR spectroscopy.

3.3 Complex Oligosaccharides Related to Glycolipids

The ^1H NMR spectroscopy principles and methodology discussed in the previous section are not only valid for glycoprotein-related carbohydrates. They apply equally well to glycolipids^{51,52} and glycosyl phosphatidyl-inositol (GPI)

anchors,⁵³ polysaccharides,²⁴ and proteoglycans.⁵⁴ Here we will limit the discussion to glycolipids. Unlike glycoproteins, glycolipids are amenable to high-resolution ^1H NMR analysis in their native state; however, they cannot be investigated in aqueous solution. Solvents such as DMSO and DMF have been successfully applied, and volumes of data that are valuable for primary structural analysis have been collected over the years. Examples of ^1H NMR databases of glycolipids in DMSO are given elsewhere.^{51,55–59}

To take advantage of the massive amount of NMR data on glycoprotein-related oligosaccharides in water, the removal of the lipid by enzymatic (endoglycoceramidase) or chemical (ozonolysis) procedures is currently employed as a standard technique for allowing the glycolipid oligosaccharides to be examined under the same circumstances as glycoprotein/glycopeptide carbohydrates and free oligosaccharides [see, for example, Figure 5(b) versus Figure 5(a)].⁶⁰

3.4 De Novo Sequencing of Glycoconjugate Carbohydrates

Although useful for the primary structural analysis of carbohydrates within the closely knit framework of structures presented abundantly by Nature for glycoprotein and glycolipid oligosaccharides, collections of chemical shifts contribute little to our understanding of NMR. However, as of the early 1980s, NMR spectroscopy provides the tools necessary to determine any novel carbohydrate structure de novo, without significant help from other techniques.

When the 1D ^1H spectrum does not resemble that of a known oligosaccharide structure, a combination of multiple pulse ^1H NMR spectroscopic techniques, primarily two-dimensional (2D) COSY, TOCSY, and NOESY or

ROESY, may be applied for the de novo sequencing of the carbohydrate.^{9,55,58} provided that 20–50 nmol of pure substance (2–5-times the amount of sample mentioned for the 1D analysis) is available for the analysis. The TOCSY technique permits subspectral editing of the ^1H spectrum for each constituting glycosyl residue^{61,62} and, consequently, the virtually complete assignment of all of the multiplet patterns in the ^1H NMR spectrum (including those in the envelope region between 3–4 ppm). Subsequently, depending on the size of the oligosaccharide and the magnetic field strength of the spectrometer used, NOESY or ROESY spectra enable the inference of the glycosyl-residue sequence, including the positions of glycosidic linkages, based on the detection of through-space connectivities.⁶³

Examples of the application of this general strategy are manifold.^{18,64–68} Because of its importance, we will briefly illustrate the strategy for a novel tetrasaccharide found O-linked to Ser₆₁ in Factor IX, a serum glycoprotein involved in the human blood clotting cascade.^{69,70} Figure 6(a) shows the 1D ^1H NMR spectrum of a glycopeptide (20 nmol) obtained from human Factor IX consisting of four glycosyl residues and nine amino acids. At the start of the NMR studies, the peptide sequence was known to be Leu₅₇–Asn–Gly–Gly–Ser–Cys*–Lys–Asp–Asp₆₅ (where Cys* indicates an *S*-carboxymethylated Cys residue). Also, it was known that the carbohydrate portion of the glycopeptide contained Gal, GlcNAc, Fuc, and Neu5Ac in equimolar ratios. In order to decipher the primary sequence of the tetrasaccharide, to pinpoint the side chain of Ser₆₁ as the site of glycosylation in the peptide, and to elucidate which of the four sugar residues was involved in the linkage to Ser₆₁, the complete assignment of the ^1H NMR spectrum of the glycopeptide was required. However, not only did the presence of the nonapeptide obscure many of the saccharide ^1H signals, it was not even possible (unlike for many other glycopeptide NMR spectra) to assign any signals in the 1D spectrum of the Factor IX glycopeptide simply by inspection. Neither the usually well-resolved structural-reporter-group signals of sugar anomeric and deoxy protons nor the amino acid H- α protons were recognizable off-hand. However, 2D correlated spectroscopy (in particular, COSY and TOCSY) was successfully applied for the identification of the spin systems of the individual sugar and amino acid residues. Figure 6(b) shows the relevant portion of the TOCSY spectrum. The resulting connectivity patterns in the COSY and TOCSY spectra were assigned to sugar and amino acid residue types based on their comparison with literature data for the individual spin systems. Subspectra for the sugar residues were traced starting from their H-1 signals (found between 4.4 and 5.5 ppm) or, in the case of Neu5Ac, from the H-3ax and H-3eq protons (expected around 1.8 and 2.7 ppm, respectively; see Figure 3). The H-1,H-2 connectivities for Gal, GlcNAc, and Fuc were particularly clear in the COSY spectrum. The TOCSY subspectra through H-1 included (in addition to the H-2 signals) the Fuc H-3, Gal H-3 and H-4, and GlcNAc H-3, H-4, H-5, and H-6/6' [Figure 6(b)].

Once the chemical shifts of 80% of the sugar protons had been established, the structural-reporter-group concept (Section 3.2) enabled the assignment of the linkage configurations and partial sequence of the four residues. The combination of chemical shifts for Neu5Ac H-3ax and H-3eq

Figure 5 (a) The 500MHz ^1H NMR spectrum (DMSO- d_6 /D $_2$ O, 98:2, v/v; 27 °C) of an intact ganglioside. (b) The 500MHz ^1H NMR spectrum (D $_2$ O, pD = 6, 23 °C) of the oligosaccharide released from the ganglioside by endoglycoceramidase digestion⁶⁰

Figure 6 (a) The 600 MHz ^1H NMR spectrum (D_2O , $\text{pD} = 7.2$, 23°C) of the Factor IX glyco-nona peptide (~ 20 nmol).⁶⁹ (b) Regions of the 2D ^1H TOCSY (mixing time 108 ms) and (c) ROESY (mixing time 200 ms) spectra of Factor IX glyco-nona peptide. The sequence of the structural entities Gal β (1 $\rightarrow$ 4)GlcNAc, GlcNAc β (1 $\rightarrow$ 3)Fuc, and Fuc α (1 $\rightarrow$ O)Ser is indicated by the vertical lines that connect ROESY and TOCSY cross peaks. The numbers in the spectra refer to the protons in the respective glycosyl residues. (d) Schematic structure of the tetrasaccharide Neu5Ac α (2 $\rightarrow$ 6)Gal β (1 $\rightarrow$ 4)GlcNAc β (1 $\rightarrow$ 3)Fuc α (1 $\rightarrow$ O)Ser₆₁ of human Factor IX. The $\bullet$ — symbolizes an OH group. Sugar ring H atoms are not shown, with the exception of the GlcNAc H-1, Fuc H-3, Fuc H-1, and Ser H- β protons in order to illustrate their spatial arrangement relevant to the observed NOE effects

at 1.72 and 2.67 ppm, known to be sensitive to the linkage in which the residue is involved and the type of sugar to which it is attached, indicated that the Neu5Ac residue was $\alpha(2\rightarrow6)$ -linked to the Gal residue (compare Figure 3). Furthermore, the Gal H-1 chemical shift of 4.43 ppm and its coupling $^3J(\text{H-1,H-2})$ of 7.8 Hz were characteristic of its involvement in a $\beta(1\rightarrow4)$ linkage to GlcNAc in a sialyl-*N*-acetylactosamine moiety. Likewise, the positions and coupling constants for the Fuc [4.92 ppm; $^3J(\text{H-1,H-2}) = 4.2$ Hz] and GlcNAc H-1 [4.71 ppm; $^3J(\text{H-1,H-2}) = 8.0$ Hz] signals indicated the involvement of these residues in α - and β -glycosidic linkages, respectively. At this point, it was evident from the NMR data that the tetrasaccharide consisted of a terminal Neu5Ac $\alpha(2\rightarrow6)$ Gal $\beta(1\rightarrow4)$ GlcNAc $\beta(1\rightarrow\bullet)$ moiety and an α -linked Fuc residue.

To complete the structural analysis of the tetrasaccharide, 2D NOE experiments were performed in order to gather information about the distance between pairs of protons and, thus, sequence information. A ROESY spectrum of the glycopeptide provided a number of transglycosidic NOEs [Figure 6(c)]. Among them were a NOE between GlcNAc H-1 and the proton resonating at 4.06 ppm assigned to Fuc H-3 by TOCSY, and a NOE between Fuc H-1 and a proton at 3.72 ppm, i.e., one of the β -protons on Ser₆₁. The aforementioned interresidue NOE effects [between the protons highlighted in the schematic structure in Figure 6(d)] pointed to GlcNAc(1 $\rightarrow$ 3)Fuc and Fuc(1 $\rightarrow$ O)Ser linkages, respectively. Thus, NMR spectroscopy allowed the unambiguous establishment of the linearity of the tetrasaccharide's structure. Fuc was found present in this tetrasaccharide as an internal residue, providing the 'bridge' between GlcNAc in the sialyl-*N*-acetylactosamine moiety and Ser in the peptide. The NMR data are therefore compatible with the structure Neu5Ac $\alpha(2\rightarrow6)$ Gal $\beta(1\rightarrow4)$ GlcNAc $\beta(1\rightarrow3)$ Fuc $\alpha(1\rightarrow\text{O})$ Ser₆₁.

The methodology described here is generally applicable for the complete primary structure analysis of carbohydrates as free oligosaccharides and as constituents of glycoconjugates; anomeric configurations and positions of all glycosidic linkages and, indeed, full sequences can be unraveled. The only potential problem is that $^1\text{H}/^1\text{H}$ transglycosidic NOEs are not always the largest magnitude interresidue NOEs. The resulting ambiguity in the definition of the linkage position, however, can be solved by ^1H -detected ^{13}C , ^1H multiple-bond correlation (HMBC) spectroscopy.⁷¹ Detailed applications of this technique for glycoprotein oligosaccharides have been described.⁷² Briefly, when ^{13}C and ^1H NMR spectroscopy are used together, NMR demonstrates its real power in the de novo delineation of carbohydrate structures from first principles. Heteronuclear ^{13}C , ^1H correlation NMR techniques are the most informative NMR experiments for carbohydrate primary structures.^{72,73} The sensitivity limitations for these types of experiments were overcome by the introduction of the ^1H -detected versions of many ^{13}C , ^1H correlated spectroscopies. The HMQC experiment, providing a one-bond ^{13}C , ^1H correlation map, is generally sufficient to assign unambiguously all resonances in the ^{13}C NMR spectrum, provided that the entire ^1H spectrum is assigned by the COSY/TOCSY approach. The tracing of long-range transglycosidic $^3J(\text{C,H})$ values from the HMBC spectrum completes the primary structural analysis by unambiguously providing the linkage positions and the sequence of the glycosyl residues in the complex carbohydrate. Heteronuclear correlation experiments also allow

the location of appended noncarbohydrate groups (such as acetates⁷⁴ and phosphates⁷⁵) in oligosaccharides. For further examples, see the article by Bush (*Polysaccharides and Complex Oligosaccharides*) in this Encyclopedia.

At the present time, the NMR methodology for nondestructively deciphering any unknown carbohydrate primary structure is available. Isolating and purifying carbohydrates in amounts sufficient to perform these analyses is currently the bottleneck to their structural characterization.

4 THE PRESENT: SOLUTION CONFORMATION AND DYNAMICS

Due to the competition of more sensitive procedures, NMR spectroscopy may not always be the method of choice for the de novo determination of oligosaccharide primary structures. However, NMR spectroscopy easily outperforms any other available method of structural analysis when molecular conformation and motional characteristics are the focus of attention, and it yields the most complete picture of oligosaccharide structure and dynamic behavior in solution. A knowledge of conformation and dynamics is essential to understanding how oligosaccharides mediate biological recognition on cell surfaces. The NMR parameters holding the key information regarding oligosaccharide conformation and flexibility include scalar and dipolar couplings, relaxation times, and chemical exchange rates. Section 4.1 discusses how these parameters can be related to internuclear distance and torsion angle information and, therefore, to pyranose ring pucker, ensembles of rotamers around bonds that allow for certain flexibility, glycosidic linkage conformation, hydrogen bonding, and rotational correlation times for molecular tumbling and internal motions. Section 4.2 highlights some of the multipulse NMR spectroscopic techniques currently used to gather the constraints required to define the conformation and dynamics of an oligosaccharide in aqueous solution. Noteworthy review articles dealing with the application of multipulse *n*D NMR for carbohydrate conformational analysis are available.^{9,18,55,58,59,64,66,72,76–78} Most of the NMR methodology reviewed in this section will be concerned with selective excitation experiments^{79,80} which, for carbohydrates, are extremely useful in the retrieval of any desired information from NMR spectra. Upon critical evaluation of this information, it becomes clear that all oligosaccharides are, to a greater or lesser extent, flexible. The number of conformers adopted by small oligosaccharides is, however, not infinitely large; even oligosaccharides that include a (1 $\rightarrow$ 6) linkage fluctuate between a relatively small number of rather well-defined conformations. As an example, the process of deriving an ensemble of conformations from a sufficiently large set of NMR constraints is illustrated for sialyl- $\alpha(2\rightarrow\text{b})$ lactose. This discussion will be followed immediately by the description of NMR experiments which are capable of revealing internal motion in an oligosaccharide for which, at first glance, all measured NMR constraints seem to favor a rigid-body model. For example, we demonstrate that sucrose, the disaccharide that for years has been the paradigm of carbohydrate rigidity in solution, more than likely experiences fast internal motion around its glycosidic bond. Finally, Sections 4.3 and 4.4 will summarize the current knowledge on glycoprotein and glycolipid carbohydrate conformations and dynamics.

Figure 7 (a) Definition of the chair conformations of d-hexopyranose rings (a = axial substituent). For most monosaccharides, the 1C_4 and 4C_1 chairs are energetically favored over any boat conformers. For example, Man and Gal typically adopt the 4C_1 chair conformation, while Fuc and Neu5Ac adopt the 1C_4 chair (called the 2C_5 chair for Neu5Ac) [see Figure 1(c)]. (b) Definition of the torsion angles ϕ and ψ around a typical glycosidic linkage [in this case, the (1 $\rightarrow$ 4) linkage in lactose]: $\phi = \text{H}-1-\text{C}-1-\text{O}-1-\text{C}-4'$ and $\psi = \text{C}-1-\text{O}-1-\text{C}-4'-\text{H}-4'$. In conjunction with ${}^3J(\text{H}-1, \text{C}-4')$ and ${}^3J(\text{C}-1, \text{H}-4')$ the NOE between H-1 and H-4' across the glycosidic bond is used for linkage conformation analysis

4.1 Three-Dimensional Carbohydrate Structure

Once an oligosaccharide's primary sequence has been elucidated, its 3D structural characterization is typically approached in the following steps: (i) the ring conformation for each of the constituent glycosyl residues is defined [see Figure 7(a)]; (ii) the intraresidue conformation is completed by attempting to define, relative to the ring, the conformation(s) of any pendant (CH_2OH and OH) groups; (iii) the conformations of each of the glycosidic linkages in the oligosaccharide are characterized [see Figure 7(b)]; and (iv) additional distance constraints which could be indicative of hydrogen bonding or other types of interaction between residues, both adjacent and nonadjacent in the primary structure, are sought. Oligosaccharide conformations are ultimately defined in terms of the relative (Cartesian or spherical) coordinates of the atoms in 3D space; these coordinates are obtained via the measurement of internuclear distances and torsion angles around bonds. The pioneering work of Solomon⁸¹ and Karplus^{13,82} has demonstrated the possibility of probing the geometry of molecules in solution via NMR by measurements of NOE effects and scalar couplings, respectively. NOE effects are dependent on internuclear distance, while scalar couplings between nuclei separated by three chemical bonds (3J) depend on the dihedral angle between two planes containing those nuclei. The advent of multidimensional and multinuclear spectroscopy enabled the measurement of a large number of homo- and heteronuclear NOE contacts and vicinal coupling constants, including those from extremely overlapped oligosaccharide NMR spectra. If a sufficient number of constraints can be obtained from

NMR, the 3D structure(s) of the carbohydrate can be computed.^{66,76,83} Carbohydrate NMR has reached a level of sophistication at which the number of detectable constraints is sometimes large enough to be incompatible with a single rigid conformer, prompting the consideration of ensemble average models. Help is then sought from molecular modeling (potential energy calculations) to provide candidate low-energy structures that may contribute to the ensemble average. Sometimes, rather deceptively, all measured constraints seem to favor one rigid conformation for the oligosaccharide in question. In these cases, it is particularly important to remember to take into consideration that J and NOE values are intrinsically motionally averaged. Perhaps more often, modeling of carbohydrates is hampered by the existence of very few detectable NOE contacts. Unfortunately, the number of detectable structural constraints usually proves insufficient to unambiguously define the carbohydrate's conformation. The latter phenomenon is most often attributed to more pronounced conformational flexibility.⁵⁸ As soon as carbohydrate NMR spectroscopists became aware of the dynamic nature of oligosaccharides, they attempted to measure NMR parameters which could be used to characterize internal motions more quantitatively. Internal motion in biomolecules can be detected and quantified by NMR spectroscopy if it occurs relatively slowly or relatively quickly compared with the overall motion of the molecule.⁸⁴ NMR parameters that can be related to internal dynamics include the temperature and magnetic-field-strength dependences of relaxation times (T_1 and $T_{1\rho}$) and cross-relaxation rates (homo- and heteronuclear NOEs).⁸⁵

4.1.1 Conformation

For the determination of pyranoid ring conformations, a complete set of vicinal ${}^3J(\text{H}, \text{H})$ couplings for the spin system suffices due to the relative rigidity of this type of ring structure. One or more intraresidue ${}^1\text{H}/{}^1\text{H}$ NOEs may be useful in refining the pyranose ring pucker. Conformations of pendant groups require the measurement of all pertinent vicinal $J(\text{H}, \text{H})$ scalar couplings [for example, ${}^3J(\text{H}-5, \text{H}-6)$ and ${}^3J(\text{H}-5, \text{H}-6')$ for CH_2OH in hexopyranoses; ${}^3J(\text{HOCH})$ couplings for OH groups]. Additionally, ${}^1\text{H}/{}^1\text{H}$ NOEs and heteronuclear scalar couplings may be measured. For the conversion of ${}^3J(\text{H}, \text{H}')$ scalar couplings into torsion angles, carbohydrate spectroscopists use the Karplus equation as parameterized by Haasnoot et al. to account for substitution and electronegativity effects along the $\text{H}-\text{C}-\text{C}'-\text{H}'$ pathway^{86,87} [see also Altona (*Vicinal Coupling Constants and Conformation of Biomolecules*) in this Encyclopedia]:

$${}^3J(\text{H}, \text{H}') = 13.22 \cos^2 \theta - 0.99 \cos \theta + \sum_i \Delta \chi_i [0.87 - 2.46 \cos^2(\xi_i \theta)] \quad (1)$$

where θ is the $\text{H}-\text{C}-\text{C}'-\text{H}'$ torsion angle, and $\Delta \chi_i$ are the Huggins electronegativities of substituent i relative to that of H. The value of ξ_i is either +1 or -1, depending on the orientation of the substituents.⁸⁶ As for the pendant groups, the conformation of the hydroxymethyl group in hexopyranoses is predominantly determined by the rotation around the C-5-C-6 bond described by the dihedral angle ω_{H} (Figure 8). As was reviewed by Bock and Duus,⁸⁸ information about the

Figure 8 Definition of the three staggered conformations for the hydroxymethyl group in d-glucopyranose. For NMR spectroscopy, ω_H is defined as the dihedral angle H-5-C-5-C-6-O-6. (In crystallography, ω is commonly defined as O-5-C-5-C-6-O-6; hence, the subscript H in ω_H when using H-5 as the reference atom.) The three staggered conformers are described as *gg*, *gt*, and *tg* (*g* = *gauche*, *t* = *trans*; the first letter in the pair refers to the O-6 position relative to O-5, the second to the orientation of O-6 with respect to C-4). Thus, *gg*, *gt*, and *tg* correspond to $\omega_H = 180^\circ$, 60° , and -60° , respectively

conformational preferences of the hydroxymethyl group can be obtained via NMR using $^3J(\text{H-5, H-6R})$ and $^3J(\text{H-5, H-6S})$ provided that the stereospecific assignment of the H-6 atoms is either known or can be achieved via NMR.⁸⁹

$$^3J(\text{H-5, H-6R}) = 13.22 \cos^2 \theta - 0.99 \cos \theta - 6.4 \cos^2(25.87 - \theta) - 0.96 \cos^2(7.96 + \theta) + 2.61 \quad (2a)$$

$$^3J(\text{H-5, H-6S}) = 13.22 \cos^2 \theta - 0.99 \cos \theta - 3.2 \cos^2(25.87 - \theta) - 3.2 \cos^2(25.87 + \theta) - 0.96 \cos^2(7.96 + \theta) + 2.61 \quad (2b)$$

If one assumes that the three low-energy staggered rotamers ($\omega_H = 60^\circ$, -60° , and 180°) (Figure 8) are the exclusive contributors to the average conformer, the measured values $[^3J(\text{H-5, H-6R})]_{\text{exp}}$ and $[^3J(\text{H-5, H-6S})]_{\text{exp}}$ are analyzed as linear combinations of the calculated values of these couplings for the pure *gg*, *gt*, and *tg* rotamers; the coefficients p_{gg} , p_{gt} , and p_{tg} in these equations are interpreted as relative populations, i.e., the mole fractions in which the respective staggered rotamers contribute to the time-averaged conformation as measured by NMR:

$$J_{\text{exp}} = p_{gg} \cdot J_{gg} + p_{gt} \cdot J_{gt} + p_{tg} \cdot J_{tg} \quad (3a,b)$$

(where J_{exp} is $^3J(\text{H-5, H-6R})$ or $^3J(\text{H-5, H-6S})$)

$$p_{gg} + p_{gt} + p_{tg} = 1 \quad (3c)$$

However, if constraints other than the two $^3J(\text{H-5, H-6})$ homonuclear couplings are available, it is not necessary to make the aforementioned assumption. More advanced methods applied to the analysis of the rotamer population around the C-5-C-6 bond use the conformational entropy (S) associated with an ensemble; S can be calculated as:

$$S = -R \sum_i p_i \ln p_i \quad (4)$$

where the sum is over all the conformations, p_i is the probability of the i th conformation occurring in the ensemble,

and R is the gas constant. Given the number of measurable NMR constraints, computerized methods attempt to maximize the conformational entropy.^{90,91}

Linkage conformations cannot be defined by $^nJ(\text{H,H}')$ measurements; their analysis requires the measurement of interglycosidic NOEs and ROEs (both $^1\text{H}/^1\text{H}$ NOE and ROE, and $^{13}\text{C}/^1\text{H}$ NOE, if possible), in combination with transglycosidic $^3J(\text{C,H})$ couplings. Distances are typically calculated as $r_{ij} = (igma_{\text{ref}}/\sigma_{ij})^{1/6} r_{\text{ref}}$, where σ_{ref} and r_{ref} are the cross-relaxation rate and the distance, respectively, of a pair of reference protons within the rigid pyranose ring system. Glycosidic bond angles are calculated from $^3J(\text{C,H})$ values according to the Karplus equation as parameterized by Tvaroska et al.⁹² (see also Mulloy et al.⁹³) based on seminal work by Perlman and co-workers.⁹⁴

$$^3J(\text{C, H}) = 5.7 \cos^2 \theta - 0.6 \cos \theta + 0.5 \quad (5)$$

where θ is the H-C-O-C torsion angle. In addition, $^1J(\text{C,H})$ values may be used to assist in the determination of bond conformations.^{95,96} If carbohydrates can be obtained uniformly or selectively ^{13}C isotopically-enriched,⁹⁷ long-range $^{13}\text{C}, ^1\text{H}$ couplings become easier to measure. In addition, $^1J(\text{C,C})$, $^2J(\text{C,C})$, and $^3J(\text{C,C})$ become detectable as conformational constraints. However, notwithstanding the advances that are being made in combining chemical and enzymatic syntheses, procedures to obtain uniformly ^{13}C isotopically-enriched ('labeled') carbohydrates, particularly glycoconjugate side chains, are by no means straightforward.

4.1.2 Hydrogen Bonding

Hydroxyl resonances in the ^1H NMR spectra of oligosaccharides in aprotic solvents such as DMSO have long been used as structural probes. However, as most biologists are primarily interested in carbohydrate conformations in aqueous solutions, only glycolipid NMR researchers have put any significant effort into investigating these signals in DMSO (Section 3.3). Although hydroxyl proton resonances in aqueous solutions of sugars were first observed over 14 years ago,⁹⁸ the utility of these protons in the conformational analysis of carbohydrates has been demonstrated only recently.^{99–103} Hydroxyl resonances potentially provide a wealth of structural information in the form of chemical shifts, J couplings, NOEs, exchange rates, and isotope shifts. However, this information is accessible only if the intermolecular exchange of OH protons with H_2O in the aqueous solvent can be slowed sufficiently. At room temperature, hydroxyl protons in aqueous solutions of carbohydrates engage in fast chemical exchange with water. Several researchers have applied mixed solvents (water/acetone and water/methanol) to study OH groups at low temperatures (-5°C to -10°C) (see, e.g., Poppe and Van Halbeek).⁹⁹ Recently, ^1H NMR studies of hydroxyl groups in dilute solutions of mono- and disaccharides in pure H_2O under supercooled (-15°C to -20°C) conditions have been reported.¹⁰¹ The chemical exchange effects under these conditions are reduced to such an extent that separate signals can be observed for each hydroxyl site; thus, all hydroxyl proton resonances can be assigned on the basis of scalar connectivities to nonlabile aliphatic protons. The scalar $^3J(\text{HOCH})$ couplings can be analyzed¹⁰³ by equations (1) and (3),⁴³ in conjunction with more advanced statistical methods. The linewidths,

temperature-shift coefficients, and coupling constants of OH protons are valuable hydration and hydrogen-bonding probes in NMR studies. H/D isotope effects of hydroxyl protons on ^{13}C resonances may be used to obtain additional evidence of the involvement of OH groups in intra- or interresidue hydrogen bonds.¹⁰⁴ Protruding farther from the glycosyl ring systems, OH protons may additionally serve as long-range sensor conformational probes which can be interrogated by NOESY and ROESY experiments of the carbohydrate in aqueous solution.^{99,105,106}

4.1.3 Dynamics

NOEs and ROEs (or, more strictly speaking, the cross-relaxation rates $\sigma^{\parallel}$ and $\sigma^{\perp}$), as well as scalar coupling constants, are time-averaged parameters when the interconversion of conformers is fast on the NMR timescale.¹⁰⁷ However, interpretation of the measured NMR constraints in terms of the existence of several conformers and their interconversion rates is not easily accomplished. An extensive use of molecular modeling is usually required.^{66,76,83,107,108} The experimental approach to the problem of flexibility involves the measurement of different relaxation rates (^{13}C and ^1H T_1 and $T_{1\rho}$, as well as $^1\text{H}/^1\text{H}$ and $^{13}\text{C}/^1\text{H}$ NOE) at a number of different frequencies (ω) in order to sample the spectral density $J(n\omega)$.^{109–112}

$$J(n\omega) = \left(\frac{2}{5}\right) \cdot \frac{\tau_c}{1 + (n\omega\tau_c)^2} \quad (6)$$

where $n = 0, 1$, or 2 , and τ_c , the rotational correlation time, is directly related to relaxation times T_1 and $T_{1\rho}$ (see, for example, Wagner and others).^{112–115} The laboratory and rotating frame homonuclear cross-relaxation rates, $\sigma^{\parallel}$ and $\sigma^{\perp}$, respectively, are expressed by equations (7a) and (7b):

$$\sigma^{\parallel} = K[6J(2\omega) - J(0)] \quad (7a)$$

$$\sigma^{\perp} = K[3J(\omega) + 2J(0)] \quad (7b)$$

where $K = 0.1 \Sigma_l \gamma^4 h^2 / 4\pi^2 r_{kl}^6$, γ is the ^1H gyromagnetic ratio, h is Planck's constant, r is the internuclear distance between nuclei k and l , and the summation index runs over all interactions.^{113,114,116} Similar expressions for $^{13}\text{C}/^1\text{H}$ cross-relaxation rates have been documented.¹¹²

Spectral density is most conveniently interpreted at the molecular level by the model-free approach of Lipari and Szabo^{117,118} in which the types of molecular motion of an oligosaccharide are distinguished by their different timescales. The total motion of the molecule is separated into the tumbling of the entire molecule (with rotation correlation time τ_o) modulated by more rapid internal (segmental) motion with characteristic correlation time (τ_i) and amplitude expressed by an order parameter (S^2):

$$J(n\omega) = S^2 \left(\frac{2}{5}\right) \cdot \frac{\tau_o}{1 + (n\omega\tau_o)^2} + (\langle r^{-6} \rangle - S^2) \left(\frac{2}{5}\right) \cdot \frac{\tau}{1 + (n\omega\tau)^2} \quad (8a)$$

where $n = 0, 1$, or 2 , $S^2 = \sum_{m=-2}^{m=2} |\langle (5/4\pi)^{-1/2} Y_{2m}(\Omega) / r^3 \rangle|^2$, $Y_{2m}(\Omega)$ are spherical harmonics functions with r and Ω

corresponding to the distance and polar angle of a given proton pair in the molecular frame; $\langle \dots \rangle$ denotes ensemble average; and $\tau^{-1} = \tau_o^{-1} + \tau_i^{-1}$. A slightly more simplified expression for $J(n\omega)$ may be used when taking only fluctuations due to molecular reorientation, but not internuclear separation, into account (Section 5.2); S^2 becomes distance independent, and equation (8a) becomes equation (8b):

$$J(n\omega) = S^2 \left(\frac{2}{5}\right) \cdot \frac{\tau_o}{1 + (n\omega\tau_o)^2} + (1 - S^2) \left(\frac{2}{5}\right) \cdot \frac{\tau}{1 + (n\omega\tau)^2} \quad (8b)$$

Either way, the generalized order parameter is a measure of the spatial restriction of the internal reorientation ($S^2 = 1$ in the absence of internal motion; $S^2 = 0$ in the presence of complete, isotropic reorientation).

Often applicable to oligosaccharides, this model predicts that, if there is significant relaxation through internal motion in the saccharide, the ratio of the NOEs (and the T_1 values) at different field strengths should differ for those protons relaxing with neighboring protons within fixed distances (i.e., neighbors on the same pyranose ring) versus those relaxing with neighbors at fluctuating distances (i.e., across the glycosidic linkage). The separation of the motions into distinct regimes is crucial to the success of this method. For internal motions to contribute significantly to the relaxation, their time scale must be fast compared with that of the overall tumbling (i.e., $\tau_o \sim 0.1$ ns for a disaccharide). Thus the internal dynamics (segmental motions) of carbohydrate molecules in solution can be assessed by NMR spectroscopy if the rearrangements occur much faster (or much slower) than the overall molecular tumbling. Physical models for the temperature dependences of τ_o , τ_i , and NOEs are in existence as well, but they are less successful in reproducing the dynamic behavior of oligosaccharides.

4.2 Di- and Trisaccharides

Analyses of the solution conformation and dynamics of carbohydrates encompass the following steps: (i) the complete assignment of ^1H and ^{13}C NMR spectra of the carbohydrate, (ii) the measurement of NOEs and vicinal couplings in order to establish spatial (distance and/or torsion angle) constraints between atoms, (iii) the measurement of ^1H and ^{13}C relaxation parameters (T_1 , $T_{1\rho}$, homo- and heteronuclear NOEs) as a function of temperature and field strength, and (iv) the evaluation of experimental data with the use of computational strategies, including statistical methods, potential energy calculations, and molecular dynamics (MD) or Monte Carlo (MC) simulations (as well as comparison with crystal structures, if available). With the application of at least two of the aforementioned steps, a large number of di- and trisaccharides have been examined, including sucrose (see below), maltose [$\text{Glc}\alpha(1\rightarrow4)\text{Glc}$],¹¹⁹ cellobiose [$\text{Glc}\beta(1\rightarrow4)\text{Glc}$],¹²⁰ lactose [$\text{Gal}\beta(1\rightarrow4)\text{Glc}$],^{97,121} melibiose [$\text{Gal}\alpha(1\rightarrow6)\text{Glc}$],¹²² gentiobiose [$\text{Glc}\beta(1\rightarrow6)\text{Glc}$] (see below), xylobiose [$\text{Xyl}\beta(1\rightarrow4)\text{Xyl}$],¹²³ mannobioses [$\text{Man}\alpha(1\rightarrow3)\text{Man}$ and $\text{Man}\alpha(1\rightarrow2)\text{Man}$],^{108,124} chitobiose [$\text{GlcNAc}\beta(1\rightarrow4)\text{GlcNAc}$], and chitotriose. For an overview of

Figure 9 Schematic structure of sialyl- $\alpha(2\rightarrow6)$ -lactose. The numbering of the carbon atoms and their substituents is indicated. The torsion angles ϕ and ψ around the (1 $\rightarrow$ 4) glycosidic bond are defined as in Figure 7(b): $\phi(\text{H-1}'\text{-C-1}'\text{-O-1}'\text{-C-4})$ and $\psi(\text{C-1}'\text{-O-1}'\text{-C-4-H-4})$. The angles ϕ and ψ around the (2 $\rightarrow$ 6) glycosidic linkage are defined as $\phi(\text{C-1}'\text{-C-2}'\text{-O-2}'\text{-C-6})$ and $\psi(\text{C-2}'\text{-O-2}'\text{-C-6-C-5})$, while ω is (O-5-C-5-C-6-O-2'); the definition of ϕ differs from that given in the legend to Figure 7(b) due to the absence of an anomeric proton in Neu5Ac. The conformation of the (1 $\rightarrow$ 4) linkage was studied by measuring $^3J(\text{H-1}',\text{C-4})$ and $^3J(\text{C-1}',\text{H-4})$ (compare Figure 14), as well as interglycosidic NOEs. Angle ϕ for the (2 $\rightarrow$ 6) linkage was studied by $^1\text{H}/^1\text{H}$ ROE and $^{13}\text{C}/^1\text{H}$ NOE experiments, while ψ for the (2 $\rightarrow$ 6) linkage was deduced from $^3J(\text{C-2}',\text{H-6R})$ and $^3J(\text{C-2}',\text{H-6S})$ measurements (Table 2). For ω around the (2 $\rightarrow$ 6) linkage, the Gal $^3J(\text{H-5},\text{H-6R})$ and $^3J(\text{H-5},\text{H-6S})$ were measured (Figure 13 and Table 1).¹⁰⁶ The Neu5Ac glycerol side-chain conformation was defined by the $^3J(\text{H-6},\text{H-7})$, $^3J(\text{H-7},\text{H-8})$, $^3J(\text{H-8},\text{H-9})$ and $^3J(\text{H-8},\text{H-9}')$ couplings (for the latter two, see Figure 12) in conjunction with the existence of a hydrogen bond between O-8 and the C-O bond of the C-1 carboxyl group.¹⁰⁶

di- and trisaccharide structures determined by X-ray crystallography, NMR spectroscopy and/or theoretical computations, the reader is referred elsewhere.^{77,125–128} Because of the importance of sialyl oligosaccharides in the biology of glycoproteins and glycolipids, an illustration is provided of the typical procedures involved in the NMR conformational analysis of a trisaccharide similar to the terminal entity found on various glycoprotein and ganglioside oligosaccharides, namely, sialyl- $\alpha(2\rightarrow6)$ -lactose [Neu5Ac $\alpha(2\rightarrow6)$ Gal $\beta(1\rightarrow4)$ Glc].¹⁰⁶ Comparisons are drawn with the conformations of Neu5Ac $\alpha(2\rightarrow3)$ Gal¹²⁹ and sialyl- $\alpha(2\rightarrow3)$ -lactose.¹³⁰ A schematic drawing of the structure of sialyl- $\alpha(2\rightarrow6)$ -lactose is shown in Figure 9, and definitions of torsion angles ϕ , ψ , ω , and other pertinent parameters are included in the legend to that figure.

4.2.1 ^1H and ^{13}C Spectral Assignments

Attractive alternatives to the 2D COSY and TOCSY techniques currently used for the complete assignment of the ^1H NMR spectrum of an oligosaccharide (Section 3.4) are their 1D selective analogs.^{79,131} Despite the overlap of $\sim 85\%$ of the aliphatic proton resonances within approximately 1 ppm in a typical carbohydrate spectrum, the resonances of the structural-reporter groups, including those of the anomeric protons, are separated and accessible for selective excitation, providing suitable entries for transfer of magnetization through scalar couplings to other protons in the spin system of a glycosyl residue. In fact, carbohydrates are often cited in the magnetic resonance literature as being used as toy systems for new selective excitation sequences (see Kupce and Freeman,¹³² for example). To reveal the entire spin system, i.e., trace the scalar connectivity from H-1 through H-6 for a hexosyl residue, two methods are currently being applied; (i) multistep correlated (relayed COSY) experiments^{133,134} in which magnetization is transferred in successive steps from

the selectively excited resonance, and (ii) isotropic mixing (TOCSY) pulse sequences^{62,135} that distribute selectively excited magnetization in a more uniform manner among coupled spins. Magnetization transfer in TOCSY experiments is more efficient than in relayed COSY experiments, which suffer from larger losses of magnetization due to T_2 relaxation; also, TOCSY signals occur as in-phase multiplets. The major obstacles to tracing glycosyl spin systems are small coupling constants (e.g., those between H-1 and H-2 in mannosyl, H-4 and H-5 in galactosyl, and H-6 and H-7 in Neu5Ac residues). In order to overcome these ‘bottlenecks’ in TOCSY experiments, researchers have applied a number of different schemes which rely on multiple selective excitation, e.g. double-TOCSY¹³⁶ or double-DANTE TOCSY¹³⁷ or relayed TOCSY¹³⁸ (where isotropic mixing is followed by a COSY step). Parenthetically, it should be mentioned that extensions of ^1H 1D and 2D techniques to 3D and 4D NMR techniques have been described for carbohydrates;^{139,140} however, full-blown 3D and 4D data acquisition is time-consuming and rarely necessary to solve a carbohydrate structural problem. (Multi-)selective 1D and 2D analogs of 3D and 4D NMR experiments^{80,141} are far more efficient methods of obtaining the desired information from a carbohydrate ^1H NMR spectrum. For example, the 2D selective analog of the 3D TOCSY-COSY experiment and the 3D selective analog of the 4D TOCSY-TOCSY-COSY experiment have been applied for tracing scalar connectivities in GlcNAc residues for medium-sized oligosaccharides.^{140,142} Pulse sequences which are successfully utilized for isotropic mixing include: MLEV-17,⁶² WALTZ-16,¹⁴³ DIPSI-2,¹⁴⁴ clean-CITY,¹⁴⁵ and mixing sequences proposed by Glaser and Drobny.¹⁴⁶ Selective excitation is accomplished by DANTE pulse trains¹⁴⁷ or any one of a variety of shaped pulses.^{79,80,148}

Once the ^1H NMR spectrum of an oligosaccharide has been assigned, the assignment of the protonated ^{13}C resonances on the basis of one-bond $^{13}\text{C},^1\text{H}$ correlation spectroscopy (e.g., HMQC) is relatively straightforward (Section 3.4). Nonprotonated ^{13}C signals can be assigned by an HMBC experiment. These ^1H -detected (or ‘inverse-detected’) schemes¹⁴⁹ allow the acquisition of correlation spectra for submillimolar amounts of carbohydrate sample within a few hours of data acquisition. Employing the combination of TOCSY and HMQC/HMBC spectroscopy, the ^1H and ^{13}C spectra of sialyl- $\alpha(2\rightarrow6)$ -lactose in D_2O have been fully assigned.¹⁰⁶

4.2.2 Distance and Torsion Angle Constraints

4.2.2.1 Ring Conformation. The establishment of pyranose ring pucker involves the accurate measurement of homonuclear vicinal scalar couplings; this is best accomplished with the use of ^1H selective excitation experiments such as 1D TOCSY [Figure 10(a)]. The signals in 1D TOCSY spectra are obtained in pure absorption if the admixture of antiphase dispersive lines is averaged out by stepwise incrementation of the isotropic mixing time¹³⁵ or by incorporation of a z filter.⁶² The values of the $^3J(\text{H},\text{H}')$ couplings acquired for sialyl- $\alpha(2\rightarrow6)$ -lactose¹⁰⁶ show each of the ring systems in the trisaccharide to be in its typical pyranose chair conformation, i.e., $^4\text{C}_1$ for Glc and Gal, $^2\text{C}_5$ for Neu5Ac [compare Figures 1(c) and 7, and Sabesan et al.].¹⁵⁸

4.2.2.2 Exocyclic Groups. In order to evaluate rotamer populations around the C-5–C-6 bond in hexopyranoses, the

Figure 10 Pulse sequences commonly used for ^1H selective excitation experiments on carbohydrates. Selective excitation uses either a composite 90° pulse¹⁵⁰ consisting of two consecutive DANTE pulse trains,¹⁴⁷ traces (a)–(d) or a DANTE- z sequence¹⁵¹ consisting of two interleaved pulse trains with different phase properties, trace (e). In all cases, $\Delta \sim 0.63t_{90}$, where t_{90} is the duration of the selective 90° pulse. The basic phase cyclings, as listed, may be extended following CYCLOPS and EXORCYCLE procedures.¹⁵² (a) 1D TOCSY or 1D ROESY experiment. Isotropic mixing is performed with¹⁴⁶ composite pulses $R = (290^\circ_x, 330^\circ_{-x}, 290^\circ_x)$ arranged into the supercycle (*RRRR RRRR RRRR RRRR*, 180°_y) analogous to the MLEV-17 sequence;¹⁵³ italicized letters indicate phase inversion of the element. The mixing time is flanked by two short (~ 2 ms) trim pulses. For mixing in the ROESY experiment, a train of short ($\sim 20^\circ$) pulses is used.¹⁵⁴ (b) 1D NOESY experiment. (c) Selective 3D TOCSY–ROESY experiment.^{150,155} (d) Double selective 3D TOCSY–ROESY experiment. The selective α pulse, when achieved with a DANTE pulse train,¹⁵⁶ can have any tilt angle in the range of 60° to 180° . The phase increment $\delta\phi$, associated with the change of offset during a finite time interval, is determined experimentally. (e) 1D experiments in H_2O solution utilizing 1–1 echo water suppression.¹⁵⁷ The DANTE- z pulse train can be used either for spin inversion or presaturation. The delay Δ determines the width of the excitation profile; typical values of Δ tailored for carbohydrate NMR spectra are 200 – $400 \mu\text{s}$. A short (~ 2 ms) spin lock pulse may serve to purge the dispersive part of the residual water signal. The experiments are typically performed in the difference mode, with pertinent shift of carrier frequencies, using a single power level of excitation (typically $t_{90} \sim 60 \mu\text{s}$)

protons in the exocyclic CH_2OH group must be assigned stereospecifically. Since the methylene protons, together with ring proton H-5, form a mutually coupled three-spin system, they can be recognized with, for example, a 2D triple quantum filtered COSY⁷⁶ or triple quantum correlated spectroscopy experiment.^{64,78,159,160} Proton multiplets from

exocyclic groups are more readily retrievable from selective 1D TOCSY spectra or, alternatively, from 1D COSY spectra recorded with a chemical-shift-selective filter.^{161,162} If the pertinent coupling constants cannot be accurately measured from such ^1H spectra, either due to extreme spectral overlap or second-order effects, then the goal can be attained with inverse ^{13}C , ^1H correlation experiments in which the proton multiplets are more likely to occur separately due to the larger chemical shift dispersion in the ^{13}C spectrum. Usually, the method of choice is the modified over-Bodenhausen experiment¹⁶³ as depicted in Figure 11(a); this selective 1D heteronuclear single quantum coherence (HSQC) experiment gives pure absorptive ^1H lineshapes. An additional advantage of this pulse sequence lies in the ease with which it can be applied selectively; this is accomplished by either replacing the first ^{13}C 180° pulse with its selective analog¹⁶⁹ or by performing t_1 incrementation in analogy to a chemical-shift-selective filter (by jittering of delay, δ).^{161,166} Application of this method to sialyl- $\alpha(2 \rightarrow 6)$ -lactose yields well separated, first-order H-9R and H-9S multiplets for the Neu5Ac side chain (Figure 12).

The stereospecific assignment of the exocyclic methylene protons is particularly critical when analyzing the conformation of a (1 $\rightarrow$ 6) linkage between two glycosyl residues [for example, the linkage between Neu5Ac and Gal in sialyl- $\alpha(2 \rightarrow 6)$ -lactose (Figure 9)]. When the stereospecifically mono-C-6 (or mono-C-9, if Neu5Ac is concerned) deuterated analogs of the oligosaccharide are available, the assignment of H-6R (H-9R) and H-6S (H-9S) is readily accomplished. However, the stereospecific chemical synthesis of a mono-C-6-deuterated analog of a mono- or disaccharide is usually a rather laborious procedure. Fortunately, NMR spectroscopy can, for some oligosaccharides, assign the C-6 methylene protons stereospecifically without the aid of deuteration. To accomplish this, one needs to be able to measure the pertinent vicinal $^3J(\text{H-5}, \text{H-6})$ and $^3J(\text{H-5}, \text{H-6}')$ coupling constants in conjunction with either the H-4/H-6,6' NOE effects⁷⁸ or the $^3J(\text{C-4}, \text{H-6})$ and $^3J(\text{C-4}, \text{H-6}')$ scalar couplings.^{89,170} The measurement of heteronuclear coupling constants will be discussed later in this section. As to the stereospecific assignment of H-6R and H-6S based on ‘NOE-labeling’, valuable spectral information can be obtained from selective analogs of 3D NOE-labeling experiments in many cases.^{80,150,171} Figure 13 shows a selective 3D TOCSY–ROESY spectrum obtained for sialyl- $\alpha(2 \rightarrow 6)$ -lactose with the pulse sequence shown in Figure 10(d). The NOE connectivities originating from Gal H-4 appear well-resolved. The values of the Gal $^3J(\text{H-5}, \text{H-6})$ coupling constants (Table 1), along with the observation of NOE between Gal H-4 and only one of the H-6 protons (Figure 13), enabled the stereospecific assignment of Gal H-6R and Gal H-6S.¹⁰⁶ Subsequent analysis of the vicinal $^3J(\text{H-5}, \text{H-6R})$ and $^3J(\text{H-5}, \text{H-6S})$ coupling constants using equations (3a)–(3c) provided the rotamer populations around ω for sialyl- $\alpha(2 \rightarrow 6)$ -lactose (Table 1). This interpretation was refined by the application of the maximum entropy method.⁹⁰ The availability of a relatively large set of structural constraints is required for this approach [for example, the values of the Gal $^3J(\text{H-5}, \text{H-6R}')$, $^3J(\text{H-5}, \text{H-6S}')$, $^3J(\text{C-4}, \text{H-6R})$ and $^3J(\text{C-4}, \text{H-6S})$ scalar couplings and the H-5/H-6R, H-5/H-6S, H-4/H-6R, and H-4/H-6S NOEs were used in the analysis of the rotameric distribution; see Table 2]. When applied to gentiobiose [$\text{Glc}\beta(1 \rightarrow 6)\text{Glc}$] to characterize the conformational flexibility around the C-5–C-6 bond which is part of the disaccharide’s glycosidic linkage,

Figure 11 Pulse sequences for measuring long-range $nJ(\text{C,H})$ ($n = 2, 3, 4, \dots$) with ^1H detection. SL denotes spin lock; the other symbols are as defined in Figure 10. (a) Modified HSQC experiment.^{163–165} The pulse marked with x is either selective or nonselective. The delay δ is either systematically or stochastically incremented¹⁶⁶ to obtain selectivity in the carbon domain. The delay τ is taken long enough for the evolution due to heteronuclear long-range couplings to become manifest. The resulting proton multiplets are in antiphase with respect to one- or multibond $^{13}\text{C}, ^1\text{H}$ couplings and in-phase with respect to homonuclear couplings. (b) Modified HSQC and (c) relay TOCSY-HSQC experiments¹⁶⁷ tailored for measuring interglycosidic $^3J(\text{C,H})$ in oligosaccharides. (d) ^{13}C -selective 2D analog of a 3D exclusive-type $^{13}\text{C}, ^1\text{H}$ correlation experiment.¹⁶⁸ The ^{13}C 90° pulses are 1–2 ms long; $\tau \sim [2^1J(\text{C,H})]^{-1}$

Figure 12 Editing ^1H multiplets according to their ^{13}C chemical shift. Spectrum of sialyl- $\alpha(2\rightarrow6)$ -lactose in D_2O solution obtained with the pulse sequence shown in Figure 11(a); τ is set to 3 ms. The Neu5Ac C-9 frequency was selected by randomly jittering the delay δ . In the ^1H spectrum of the ^{12}C -9 isotopomer, H-8–H-9S–H-9R constitute a second-order ABX spin system; no value for the homonuclear coupling $^3J(\text{H-8, H-9S})$ can be derived from that spectrum (reproduced with permission from Escom Science Publishers)¹⁰⁶

the maximum entropy method yields results that differ significantly from the results of traditional rotameric distribution calculations employing force-field-based analysis of the $^3J(\text{H-5, H-6})$ couplings by a Karplus-type equation;⁹⁰ however, for sialyl- $\alpha(2\rightarrow6)$ -lactose that difference was insignificant.

4.2.2.3 Linkage Conformations from $^3J(\text{C, H})$. Long-range heteronuclear scalar couplings [$^3J(\text{C, H})$] through the glycosidic bonds ($\text{H}-\text{C}-\text{O}-\text{C}'$ and $\text{C}-\text{O}-\text{C}'-\text{H}'$) [Figure 7(b)] provide spatial constraints for the torsion angles ϕ and ψ , respectively, around the glycosidic linkages. Most of the NMR pulse sequences developed for the sensitive and accurate measurement of $^3J(\text{C, H})$ values for carbohydrates are based on the ^1H -detected HSQC experiment.^{163,164} The experiments can be conducted in true 2D or selective 2D mode by selective excitation and/or chemical-shift filtering of the protons and/or carbons of interest^{167,169,172} (Figure 11). If the proton of interest is not accessible for selective excitation, the anomeric proton of the relevant monosaccharide is excited first, and the magnetization is transferred to the desired proton by a TOCSY step preceding the HSQC experiment [Figures 11(c) and 14].¹⁶⁷ With the aid of these methods, the pertinent $^3J(\text{Glc C-4, Gal H-1})$ and $^3J(\text{Glc H-4, Gal C-1})$ couplings in sialyl- $\alpha(2\rightarrow6)$ -lactose were determined to be 4.2 and 5.1 Hz, respectively (Table 2).

As a valuable alternative to HSQC, a double INEPT type polarization transfer step may be used in the ^1H -detected measurement of long-range $^{13}\text{C}, ^1\text{H}$ couplings; examples of such ^1H - and ^{13}C -selective, ^1H -detected 2D and pseudo 2D experiments have been reported.¹⁷³ Selective and nonselective measurements of interglycosidic $^3J(\text{C, H})$ are greatly facilitated by the incorporation of ^{13}C labels at the positions involved in glycosidic linkages, as was demonstrated for sucrose.¹⁷⁴

The elusive long-range heteronuclear scalar coupling parameters are also present in 2D ^{13}C -filtered $^1\text{H}, ^1\text{H}$ correlation spectra, e.g., TOCSY¹⁷⁵ and NOESY/ROESY spectra,¹⁷⁶ which

Figure 13 Selective 3D TOCSY–ROESY spectrum of sialyl- $\alpha(2\rightarrow6)$ -lactose in D_2O solution (~ 30 mM) obtained with the pulse sequence shown in Figure 10(c) at 500 MHz and ambient temperature. The Gal H-1 proton was selectively excited (for 60 ms), followed by 77 ms of TOCSY and 140 ms of ROESY mixing. The digital resolution in the resulting 2D spectrum is 0.73 Hz pt^{-1} and 4.3 Hz pt^{-1} in the ω_2 and ω_1 dimensions, respectively; the total acquisition time was less than 5 h (reproduced with permission from Escom Science Publishers)¹⁰⁶

Table 1 Rotamer Distribution around Gal C-5–C-6 in Sialyl- $\alpha(2\rightarrow6)$ -Lactose

Coupling constant	4 °C	21 °C	77 °C
$^3J(\text{H-5, H-6R})$	8.5 ± 0.2	8.3 ± 0.2	7.8 ± 0.2
$^3J(\text{H-5, H-6S})$	3.7 ± 0.2	3.8 ± 0.2	4.2 ± 0.2
Population ^a	4 °C	21 °C	77 °C
p_{gg}	0.18 ± 0.03	0.20 ± 0.03	0.22 ± 0.02
p_{gt}	0.74 ± 0.03	0.71 ± 0.03	0.64 ± 0.02
p_{tg}	0.08 ± 0.03	0.08 ± 0.03	0.14 ± 0.02

^aCalculated from the vicinal coupling constants $^3J(\text{H-5, H-6R})$ and $^3J(\text{H-5, H-6S})$ using equations (3a)–(3c). See Figure 8 for explanation of gg , gt , tg notation.

exhibit an exclusive type cross-peak structure. In these spectra, the long-range coupling constants are measured in the ω_2 dimension as a displacement of the proton multiplets that are resolved in the ω_1 dimension by the (large) $^1J(\text{C, H})$ coupling. One-dimensional versions of this experiment have been applied to carbohydrates^{89,177} to measure, for example, the $^3J(\text{C-4, H-6R})$ and $^3J(\text{C-4, H-6S})$ scalar couplings in glucose and galactose residues. Alternatively, a ^{13}C -filtered ROESY experiment has been introduced to measure $^3J(\text{C, H})$ coupling constants through the glycosidic bonds of a cyclic glucan.¹⁷⁸

Figure 14 The measurement of heteronuclear long-range coupling constants across a glycosidic linkage illustrated for lactose in D_2O (50 mg mL^{-1}). (a) Reference spectrum. (b) Spectrum obtained with the pulse sequence shown in Figure 11(b). A 1H composite pulse of 60 ms was applied selectively at Gal H-1, while the Glc ^{13}C -4 selective pulse was 2 ms long. (c) The heteronuclear coupling $^3J(C-4, H-1')$ causes the antiphase pattern of the observed Gal H-1 multiplet. It is evident from the 1D TOCSY traces (d), (e), and (f) that $^3J(C-1', H-4)$ cannot be obtained via the experiment shown in Figure 11(b) (note the overlap of Glc H-4 with Gal H-3); therefore, a relay TOCSY-HSQC experiment [Figure 11(c)] in which magnetization was selectively transferred from Glc α H-1 to H-4 was necessary (trace g). The duration of the entire pulse sequence in Figure 11(c) was close to 200 ms; 5500 scans were accumulated. (h) The heteronuclear coupling $^3J(C-1', H-4)$ is read from the antiphase structure of the observed Glc α H-4 multiplet, computer-simulated in trace (i). The values $^3J(C-4, H-1')$ and $^3J(C-1', H-4)$ are 4.0 and 5.1 Hz, respectively (reproduced with permission from Academic Press)¹⁶⁷

These methods, successfully applied to oligosaccharides with a natural abundance of ^{13}C , show their greatest potential in the measurement of long-range heteronuclear scalar couplings in ^{13}C isotopically-enriched carbohydrates (cf. Montelione et al.).¹⁷⁹ The pulse sequence in Figure 11(d) presents the selective version of 3D experiments originally designed for measurements of heteronuclear couplings in isotopically-enriched proteins.^{179,180} The long-range carbon–proton coupling constants are measured independently of the linewidth from the exclusive-type scalar couplings correlation patterns,^{168,179,180} as demonstrated (Figure 15) for glucose, 99% ^{13}C -labeled at

Table 2 Average Distances and Vicinal Coupling Constants for Sialyl- $\alpha(2\rightarrow6)$ -Lactose in Aqueous Solution¹⁰⁶

^aThe distances r_{app} were evaluated with the formula $r_{ij} = r_{kl}(I_{kl}/I_{ij})^{1/6}$, in which I_{ij} and I_{kl} are the integrated signal intensities; I_{kl} corresponds to a reference interaction. For ROESY spectra, the intensities were scaled by the offset dependent factors $(\sin \theta_i \cdot \sin \theta_j)^{-2}$, in which $\theta_i = \arctan(\omega_i/(\gamma B_1))$; ω_i represents the offset from the carrier frequency and $\langle \gamma B_1 \rangle$ the effective field strength in Hz. The precision of the distances is estimated to be $\sim 0.1r$.

^bThe precisions of the J_{exp} values are ± 0.2 Hz, except those of $^3J(C-1, H-4)$ (± 0.4 Hz) and $^3J(C-4, H-6R)$ and $^3J(C-4, H-6S)$ (± 0.2 Hz).

^cMMC simulated distances¹⁰⁶ were calculated according to the formula $\langle r^{-3} \rangle^{-1/3}$. The $\langle r_{sim} \rangle$ and J_{sim} values were scaled to 27 °C.

^dFamily I corresponds to the MMC simulation that started with ϕ of the (2→6)-linkage being set to -60° ; for family II, the pertinent angle was set to 180° .

^eThis distance reflects the occurrence of a hydrogen bond between Neu5Ac OH-7 and Glc O-3.

^fSee Table 1.

^gCompare with Figure 14.

^hAn anomerization effect ($\Delta\delta_{\alpha-\beta}$) was observed for Gal H-6R, but not for Gal H-6S, indicating that the former proton is closer to the Glc reducing end, i.e. near O-3 of the Glc residue; see Figure 16.

C-1. Furthermore, the direction of the multiplet displacements allows the determination of the signs of the relevant coupling constants (cf. Serianni and Podlasek).¹⁸¹

4.2.2.4 Linkage Conformations from Interresidue $^1H/^1H$ NOE. Early in the history of carbohydrate NMR, conformational studies of small and medium-sized oligosaccharides in solution were based on steady-state NOE measurements.¹¹³

Figure 15 The measurement of heteronuclear coupling constants $nJ(\text{C-1}, \text{H})$ within glucose, ^{13}C -labeled at C-1, utilizing the pulse sequence shown in Figure 11(d). The heteronuclear couplings are read from the chemical shift difference between corresponding upper and lower multiplets. The digital resolution in the ω_2 domain is 0.055 Hz pt^{-1} , allowing the $^4J(\text{C-1}, \text{H-6R})$ and $^4J(\text{C-1}, \text{H-6S})$ couplings to be determined as 0.2 ± 0.05 and $0.4 \pm 0.1 \text{ Hz}$, respectively

The major disadvantage of this approach lies in the fact that weak, direct interactions are frequently obscured by indirect effects and, thus, escape observation. More recent studies are based on measurements of cross-relaxation rates between two nuclei. Values for these parameters can be obtained either from multiselective relaxation time measurements¹¹⁵ or analyses of 1D transient or 2D NOESY spectra.¹¹⁴ The cross-relaxation rates are extracted from NOESY experiments on the basis of the two-spin approximation¹⁸² or by ‘full relaxation matrix analysis’.¹⁸³ The latter method has proven to be the most reliable in conformational analyses of carbohydrates.⁶⁶ Selective 1D NOESY experiments can give accurate (within 3%) estimations for cross-relaxation rates in small and medium-sized oligosaccharides, even at long mixing times. Moreover, selective spectra are free from zero quantum interferences which particularly obscure analysis of 2D NOESY spectra at short mixing times. Another crucial issue in quantitatively analyzing NOE data lies in their avoidance of contamination by indirect magnetization transfers. Undesired three-spin effects can be eliminated by (multi-)selective irradiation of potential mediators of spin diffusion during the NOESY mixing time.¹⁸⁴

In order to overcome the problem of trying to detect vanishingly small NOE effects for tri- and tetrasaccharides at $\sim 400\text{--}500 \text{ MHz}$, a novel technique for measuring cross-relaxation rates in the rotating frame was proposed. After its first application to a tetrasaccharide,⁶³ the technique’s name was changed from CAMELSPIN to ROESY¹⁸⁵ spectroscopy and steadily gained the confidence of NMR spectroscopists as being an invaluable addition to the assortment of techniques used for the conformational analysis of molecules of all sizes. A major problem in the quantitative analysis of ROESY spectra are Hartmann–Hahn effects which occur in coupled spin systems.^{154, 186} These effects can, however, be minimized experimentally by a judicious choice of the carrier frequency.¹⁵⁴ An important feature of ROESY spectra is that NOE and chemical-exchange-mediated magnetization transfers

can be readily distinguished.^{187, 188} Sialyl- $\alpha(2\rightarrow6)$ -lactose, when investigated at 500 MHz and ambient temperature, is characterized by laboratory frame $^1\text{H}/^1\text{H}$ NOEs close to zero. Therefore, most of the distance constraints listed for the trisaccharide in Table 2 were obtained via 1D selective ROESY experiments.¹⁰⁶

4.2.2.5 Hydrogen Bonding. The detection of intramolecular hydrogen bonds requires the observation of chemical shifts, linewidths, temperature shift coefficients, NOEs, and, if possible, $^3J(\text{HOCH})$ couplings and exchange rates of assigned OH signals. In order to use OH protons as conformational probes for oligosaccharides, special techniques for water suppression must be utilized.^{157, 189–191} Additionally, isotope effects on ^{13}C chemical shifts examined in $\text{H}_2\text{O}/\text{D}_2\text{O}$ (1:1, v/v) may be interpreted in terms of hydrogen bonding.¹⁰⁴

If chemical exchange rates are of the same order of magnitude as the vicinal coupling constants, the assignment of hydroxyl protons on the basis of scalar correlation spectroscopy will not be possible. In these cases, assignments can be based on spatial proximities to the ring protons gained from steady-state NOE spectra [see Figure 10(c) for the pulse sequence]. This procedure requires, however, a good deal of caution, as spin diffusion and NOE enhancements mediated by chemical exchange could lead to erroneous assignments. In mixed solvents at temperatures well below 0°C , chemical exchange is often retarded to an extent that transient NOE techniques can be utilized. As may be expected, even at low temperatures, the $^3J(\text{HOCH})$ couplings for mono- and disaccharides obtained are found to be indicative of rotational averaging of the ‘dangling’ hydroxyl groups in most cases.¹⁰³ However, NOESY experiments performed on supercooled di- and trisaccharides strongly suggest that the majority of the intramolecular hydrogen bonds inferred from their crystal structures persist in solution.¹⁰¹

Most of the OH signals of sialyl- $\alpha(2\rightarrow6)$ -lactose, investigated in mixed solvent systems at temperatures as low as -12°C and in $\text{H}_2\text{O}/\text{D}_2\text{O}$ at 1°C , were assigned by 1D steady-state NOE experiments. Based on their linewidths and temperature shift coefficients (in conjunction with isotope shift effects observed in the ^{13}C spectra of the trisaccharide in $\text{H}_2\text{O}/\text{D}_2\text{O}$), three OH groups were found to be involved in intramolecular hydrogen bonds. First, Neu5Ac OH-8 is involved in an intrasidue hydrogen bond to the C-1 carboxyl group;⁹⁹ secondly, the hydrogen bond between Glc OH-3 and Gal O-5 is reminiscent of that found in lactose,¹⁰¹ both in solution and in the crystal structure. Finally, the hydrogen bond observed between Neu5Ac OH-7 and Glc O-3 is an example of a long-range structural constraint of great value in the construction of the preferred conformation of sialyl- $\alpha(2\rightarrow6)$ -lactose in aqueous solution. Modeling of the trisaccharide was based on 25 interresidue NMR constraints (Table 2). Analysis by MMC simulations^{106, 192} has shown that sialyl- $\alpha(2\rightarrow6)$ -lactose occurs predominantly in two families of conformers that differ in the ϕ angle around the $(2\rightarrow6)$ -linkage (-60° versus 180°). The average structure of the predominant ($>80\%$) family of conformers is depicted in Figure 16; it is the family stabilized by the three intramolecular hydrogen bonds.

4.2.3 Dynamics

The 3D structure of the disaccharide sucrose [$\text{Fru}\beta(2\leftrightarrow1)\alpha\text{Glc}$] (Figure 17), particularly the conformation of its glycosidic linkage, has been the subject of numerous investigations.

Figure 16 Stereo plots [ball-and-stick (b), Dreiding models (c), CPK models (d)] of the predominant conformer ('family I', Table 2) of sialyl- $\alpha(2\rightarrow6)$ -lactose (a) in aqueous solution as derived from NMR data.¹⁰⁶ The Neu5Ac O-7::H::Glc O-3 and Glc O-3::H::Gal O-5 hydrogen bonds are clearly visible

Data obtained on sucrose in the crystalline^{193,194} and solution states^{93,174,195} have led to uncertainties concerning the degree of rigidity of the linkage conformation in solution, thus posing the question whether it is the same as in the crystal structure. A great deal of effort was spent examining intramolecular hydrogen bonding^{196,197} and its effect, if any, on the overall conformation of sucrose in solution. McCain and Markley¹⁹⁸ were the first to measure ^{13}C T_1 relaxation times on sucrose as a function of the magnetic field strength. They realized the importance of knowing the timescale of internal motion when modeling carbohydrate conformations. As discussed in

Section 4.1.3, this information can, in principle, be gained from nuclear relaxation rate measurements, preferably at different field strengths and different temperatures. The number of such studies performed on carbohydrates is remarkably small, and a model rigid on the timescale of molecular reorientation is often assumed on the basis of ^{13}C T_1 relaxation times. Accordingly, McCain and Markley's careful ^{13}C T_1 measurements for sucrose revealed very fast and small amplitude torsional and vibrational motions^{198–200} and different mobility of exocyclic groups;²⁰⁰ however, the glycosidic linkage was judged to be rigid on the basis of this type of measurements, and similar in conformation to that observed in the crystalline state. Presenting a quantitative analysis of the field strength dependence of $^1\text{H}/^1\text{H}$ NOE data, Poppe and Van Halbeek¹⁰⁵ questioned the rigidity of the sucrose glycosidic bond in solution and explained the reasons why this type of flexibility was not revealed by McCain and Markley's data. The evidence is briefly reviewed below.

Seeking to reveal as large a set of interresidue distance constraints as possible and to shed light on the existence of any hydrogen bonds in sucrose in aqueous solution, sucrose was investigated at low temperatures in aqueous solutions with the purpose of including the OH signals in the analyses. All of the sucrose OH signals were indeed observed in 1–1 echo experiments [Figure 17(a)], and had lines sufficiently narrow to be assigned by 2D and selective 1D TOCSY experiments. To measure interresidue distance constraints, 1D ROESY [Figure 10(a)] and multiselective TOCSY–ROESY [Figure 10(d)] experiments were performed; these experiments benefited from the excellent water suppression by an inhomogeneous, transverse B_1 field [see Figure 17(b–f)]. The concept of selective 3D TOCSY–NOESY and TOCSY–ROESY spectroscopy [as mentioned for the assignment of the Gal H-6 protons in sialyl- $\alpha(2\rightarrow6)$ -lactose, Figure 13] was extended to include multiple selective excitations. In an analogous manner to a 1D NOE experiment, these experiments allowed the measurement of NOEs between H-5 g and its spatial neighbors, in addition to NOEs between H-1 g and its neighbors ('g' denotes the glucose, 'f' the fructose moiety in sucrose). An example of a double selective pseudo 3D TOCSY–ROESY spectrum of sucrose is shown in Figure 17(c). Selective excitation of the H-4 g resonance was followed by a TOCSY step, a second selective pulse applied to the H-5 g resonance, and finally a ROESY step. Thus, NOE connectivities originating from H-5 g, which could not have been excited in a single selective experiment, were successfully measured. Special care was taken to ensure that NOEs were free of spin diffusion artifacts before converting them into distances. The standard 1D NOESY spectrum of sucrose after selective excitation of the H-1 g resonance [Figure 18(a)] revealed NOE enhancements to H-11'f, H-66'f, H-4f, H-5f, and H-3f. To determine the amount of the H-1 g/H-3f NOE due to direct magnetization transfer, H-11'f, H-4f, and H-5f were selectively and simultaneously spin locked during the mixing time of a second experiment [Figure 18(b)], thereby cutting off all possible indirect magnetization transfer pathways from H-1 g to H-3f. The results of the quantitative NOE measurements are compiled in Table 3. Interestingly, all NOE connectivities (and the lone exchange interaction, see below) found for sucrose in water solution

Figure 17 500 MHz ^1H NMR spectra of sucrose [$\text{Fru}\beta(2 \rightarrow 1)\alpha\text{Glc}$; $g = \text{Glc}$, $f = \text{Fru}$] (5 mg in 0.5 ml of $\text{H}_2\text{O}/(\text{CH}_3)_2\text{CO}$, 6:1, v/v) obtained at -10°C (except trace f). (a) Spectrum obtained with a 1–1 echo pulse sequence. (b) 1D ROESY spectrum (320 scans) obtained with the pulse sequence shown in Figure 10(a); selective excitation of the H-1g resonance was followed by a 200 ms spin lock pulse train. (c) Double-selective 3D TOCSY–ROESY spectrum obtained with the pulse sequence shown in Figure 10(d). Selective irradiation of H-4g was followed by 30 ms of isotropic mixing, the selective irradiation of H-5g, and a 200 ms spin lock pulse train; 640 scans were accumulated. (d, e) 1D ROESY spectra (320 scans) with selective irradiation of OH-1f and OH-2g, respectively. (f) 1D ROESY spectrum, recorded at -6°C , with selective irradiation of OH-2g. A comparison of traces (e) and (f) reveals an OH-2g/OH-1f chemical exchange interaction, suggesting the existence of an O-1f::O-2g hydrogen bond in solution under the applied conditions¹⁰⁵

can be explained in terms of a single conformation, which is virtually identical to that in its crystal structure.

However, when measuring specific $^1\text{H}/^1\text{H}$ cross-relaxation rates as a function of magnetic field strength and temperature, large conformational changes occurring much faster than the overall motion were revealed around the glycosidic bond.¹⁰⁵ Selective excitation at the H-1g resonance was followed by the detection of NOEs at H-11'f, H-4f, and several protons in the glucopyranose ring. The NOEs between protons on different rings proved to be field-strength-dependent, while this did not seem to be the case for NOEs between protons in the glucopyranose ring [Figure 18(c)]. This observation is interpreted as evidence for the occurrence of rearrangements around the glycosidic bond between the glucosyl and fructosyl residue which are much faster than the tumbling time of the molecule in solution ($\tau_0 \sim 0.2$ ns). This type of internal motion is transparent

Figure 18 (a) 1D NOESY spectrum (500 MHz; $\tau_{\text{mix}} = 0.4$ s) of sucrose [$\text{Fru}\beta(2 \rightarrow 1)\alpha\text{Glc}$; $g = \text{Glc}$, $f = \text{Fru}$] in a $\text{D}_2\text{O}/(\text{CH}_3)_2\text{CO}$ (6:1, v/v solution) at -5°C . The interresidue NOE enhancements of fructose ring protons obtained after selective excitation of Glc H-1 are indicated [see the pulse sequence in Figure 10(b)]. (b) Identical to (a), with the addition of the triple-selective spin locking of H-4f, H-5f, and H-11'f (marked with arrows) during the mixing time using a triple-DANTE pulse train. As all possible indirect magnetization transfer pathways from spin H-1g to spin H-3f are cut off in experiment (b), the measured H-1g/H-3f NOE enhancement is solely the result of direct dipolar interaction between these two spins. (c) Distances $r_{\text{H-1g-H-4f}}$ and $r_{\text{H-1g-H-1f}}$ as determined from 1D NOESY and 1D ROESY measurements on sucrose in H_2O solution at two different temperatures (-1°C and 12°C) and four magnetic field strengths (250, 400, 500, and 600 MHz). Theoretical values for $r_{\text{H-1g-H-4f}}$ (dotted lines) were predicted from a model described by Poppe and Van Halbeek,¹⁰⁵ assuming rapid interconversion of three different rotameric conformations around the glycosidic linkage

Table 3 $^1\text{H}/^1\text{H}$ Distances for Sucrose in Aqueous Solution Derived from Interglycosidic NOE Contacts¹⁰⁵

Proton pair ^a	Distance ^b (Å)
H-1g/H-1f	2.6 ^c
H-1g/H-3f	4.6
H-1g/H-4f	3.5 ^c
H-1g/H-6f	4.0
H-5g/H-4f	3.0
H-1g/OH-1f	3.6
H-1g/OH-6f	3.4
H-1g/OH-3f	4.0
H-5g/OH-3f	3.8
OH-2g/H-1f	3.2

^aData for aliphatic protons were acquired at 27 °C, data for hydroxyl protons at −10 °C; ‘g’ denotes the glucosyl, ‘f’ the fructosyl ring.

^bDistances were calculated using the formula $r_{ij} = (\sigma_{\text{ref}}/\sigma_{ij})^{1/6} r_{\text{ref}}$ in which σ_{ref} and r_{ref} represent the cross-relaxation rate of and the distance between a reference pair of protons. Intraglucosyl distances H-1g/H-2g (2.4 Å), H-1g/H-3g (3.7 Å), and H-1g/H-4g (4.0 Å) were used as references. The precision of the distances r_{ij} is estimated to be 0.1r.

^cSee Figure 18(c).

to relaxation parameters, including ^{13}C T_1 , if it occurs on the timescale of overall molecular tumbling; this seems to be the case for sucrose at ambient temperature. Thus, the accurate measurement of ^1H cross-relaxation rates ($\sigma_{\text{H,H}}$) has the following advantages over traditional ^{13}C T_1 measurements: (i) a higher spectral sensitivity; (ii) an increased ability to detect internuclear fluctuations; (iii) a dependence on spectral density at zero frequency and, therefore, sensitivity to slow motions, and (iv) the greater diversity of geometric orientations of the H–H vectors in a rigid pyranose ring, as compared with the parallel orientation of most of the C–H vectors, allowing more efficient sampling of spectral densities.

Additionally, the observation of chemical exchange between OH-1f and OH-2g [Figures 17 (e) and (f)] provides reasonable evidence for the existence of an OH-1f::O-2g hydrogen bond in solution under the applied conditions. In summary, it appears that intramolecular hydrogen bonding in sucrose is concentration-dependent; the existence of hydrogen bonds OH-1f::O-2g, OH-3f::O-2g, and OH-6f::O-5g at higher concentrations has been postulated, based inter alia on ^{13}C isotope effects.¹⁹⁶ The existence of the first two hydrogen bonds at high concentration in solution implies flexibility and fast interconversion between two conformers around the glycosidic linkage in solution (in the crystal only OH-1f::O-2g and OH-6f::O-5g are observed).

Once fast internal motion in sucrose was detected by measuring a number of interglycosidic NOEs as a function of magnetic field strength and temperature of the solution,¹⁰⁵ similar observations were reported for other di- and trisaccharides.^{201–204} It is now widely accepted that small oligosaccharides are flexible molecules, experiencing intramolecular rearrangements that are fast compared with the overall tumbling of the molecules.

4.3 Glycoprotein Oligosaccharides

Although, during the past decade, NMR spectroscopy has become sophisticated enough to handle conformational

analysis of glycoprotein-related oligosaccharides and glycopeptides in solution, few of these oligosaccharides have yet been examined as rigorously as the di- and trisaccharides mentioned in Section 4.2. In hindsight, the relatively slow pace in which oligosaccharide conformational analysis has developed is primarily due to glycobiologists’ expectations concerning the models for glycoprotein carbohydrates; they expected a single, rigid 3D shape for an oligosaccharide of any given primary structure. This school of thought was based on pioneering investigations of the ABH and Lewis blood group determinants [for primary structures see Figure 1(d)]. However, as it turned out later, these branched tri- and tetrasaccharide epitopes happened to be far more rigid than most small oligosaccharides, leading to the misguided concept of carbohydrate 3D structural rigidity and the resultant overconfidence that modeling of any carbohydrate could be handled by the HSEA approach (hard-sphere representation of nonbonded interactions dominated by the *exo*-anomeric effect). Most glycoprotein oligosaccharides are flexible to some degree and are continually experiencing dynamic fluctuations in structure. Their flexibility is important because it may allow them to fit into the binding sites of carbohydrate-binding proteins (lectins, antibodies, receptors) (Section 5.3). In chronological order, we will summarize the work on blood group oligosaccharides which are known to occur in the peripheral portions of glycoprotein and ganglioside carbohydrate chains, followed by more typical *N*-type and *O*-type glycoprotein carbohydrate structures (Figure 1).

4.3.1 Peripheral Epitopes

The conformations of blood group oligosaccharides were first investigated by Lemieux et al.,²⁰⁵ who reported ^1H and ^{13}C NMR assignments for trisaccharide fragments of the oligosaccharides denoted A, B, H, Le^x, and Le^y in Figure 1(d). Qualitative NOE data, along with primitive conformational energy calculations, were thought to indicate single conformations for each of these oligosaccharides. The influence of hydrogen bonding and other electrostatic effects was proposed to be unimportant; the rigid conformations were thought to be mainly determined by steric or nonbonded interactions and by torsional potentials.²⁰⁶

With the advent of more sophisticated NMR techniques, as well as a less naive approach to oligosaccharide modeling, Bush and co-workers set out to apply much more rigorous tests to these proposals in the late 1980s. This group of investigators acquired large collections of carefully measured NOE data on blood group and related oligosaccharides in various solvents at a number of sample temperatures.^{207–215} Full relaxation matrix analysis of those data, along with MD simulations, revealed that the blood group epitopes found on glycoproteins and glycolipids assume relatively rigid conformations. The latest results obtained by Bush and co-workers on the Le^x trisaccharide and sialyl-Le^x tetrasaccharide^{208,216} indicate that the Le^x portions of the molecules are rigid, but the Neu5Ac α (2→3)-linkage shows transitions between two predominant conformational states [experimentally defined by ROE and $^3J(\text{C,H})$ values]. Other investigators^{217,218} concur with these findings on the issue of the rigidity of the Le^x portion of the molecule [i.e., the conformation can be described by one set of ϕ, ψ -values for the Fuca α (1→3)GlcNAc and Gal β (1→4)GlcNAc linkages each] and support a model featuring fast exchange between two different conformations

of the Neu5Ac α (2 $\rightarrow$ 3)Gal-linkage. The dynamics of fucosyl- α (1 $\rightarrow$ 2)-lactose and related oligosaccharides are currently being reinvestigated along the lines discussed in Section 4.2^{203,204}

4.3.2 *N*- and *O*-Type Glycoprotein Oligosaccharides

The NOE-based conformational analysis of *N*-type glycoprotein oligosaccharides began simultaneously and independently in Toronto^{219–222} and Oxford.²²³ The conformations of the various linkages in the diantennary *N*-acetylglucosamine-type oligosaccharide [Figure 1(b)] and its high-mannose analogs were evaluated and, at first, judged to be fairly rigid with the exception of the α (1 $\rightarrow$ 6)-linkage. In 1987, however, both the Toronto^{224–226} and the Oxford^{227–229} groups realized that they had proposed ‘virtual conformations’ for the *N*-type core structures up to that point. When carefully scrutinized, the increased amount of NOE constraints available at that time appeared to be inconsistent with one conformation per linkage and prompted a reevaluation of the concept of carbohydrate structure rigidity. The ensemble representation was introduced for the oligosaccharides, as NMR observables calculated as ensemble averages gave better agreement with experimental values than those derived from single structures. Since then, MD simulations and NOE measurements at different field strengths have been helping each other over a number of ‘barriers’ to the further understanding of glycoprotein carbohydrate dynamics. Both the Oxford and the Toronto groups have recently resorted to small di-, tri- and tetrasaccharide building elements of the *N*-type oligosaccharides in order to assess carefully their dynamic behavior, while simultaneously attempting to improve the molecular modeling methods for carbohydrates.^{76,107,108,201,230–234} Currently, detailed NMR studies on larger *N*-type oligosaccharides covalently linked to proteins are being conducted as well (Section 5.1). Impartial review articles^{18,66,83,235} keep the glycobiology community abreast of continuing developments in this area of research.

Additional insight into the conformation of the core pentasaccharide Man₃GlcNAc₂ in an *N*-type glycopeptide was provided by a study of a hen ovomucoid glycodecapeptide.²³⁶ TOCSY and NOESY experiments on the glycopeptide in H₂O, supported by ³*J*(N,H) data, provided evidence that the C-2–N-2 bond in Asn-linked GlcNAc is rigid; however, this rigidity could not be attributed to any intramolecular hydrogen bond. Although these and other sophisticated tricks of the NMR trade are just beginning to be applied to larger oligosaccharides and glycopeptides, we now have a reasonable picture of the conformation and flexibility of *N*-type oligosaccharides of the high-mannose and the *N*-acetylglucosamine type. Similar investigations of *O*-type Ser/Thr-linked oligosaccharides^{78,237,238} and small sialyl oligosaccharides (Section 4.2) are currently being conducted. Given the similarities of the backbone and peripheral structural elements of *N*-type and *O*-type oligosaccharides, the results should be applicable to both classes of glycoprotein carbohydrates.

4.4 Glycolipids and Glycolipid-Related Oligosaccharides

Oligosaccharides released from gangliosides and other glycolipids (by endoglycoceramidase digestion or ozonolysis) are amenable to, and have been investigated by, the same NMR

Figure 19 Subspectral editing of the ¹H NMR spectrum (600 MHz) of the GD_{1a} oligosaccharide in D₂O [16 mg mL^{−1}] by 1D TOCSY [see the pulse sequence in Figure 10(a)]. The H-1 signals of the hexosyl residues and the H-3ax signals of the Neu5Ac residues, respectively, were selectively excited. Superscripts in Gal³ and Gal⁴ refer to the position of the linkage in which these residues are involved (ext = external; int = internal). The constant isotropic mixing time was 370 ms; 160 scans were accumulated per spectrum

techniques as mentioned for glycoprotein oligosaccharides (Section 4.3). For example, the 1D TOCSY subspectra of the Gal and Neu5Ac residues in the GD_{1a} oligosaccharide (Figure 19) serve to illustrate that, despite the abundance of small couplings, magnetization can be propagated over the entire spin system of each residue allowing the complete assignment of these spectra. The conformations of the oligosaccharide portions of gangliosides such as GM₁, GM₂, GD_{1a} (for primary structures, see Figure 1), and GPI anchors^{239,240} have been studied in aqueous environments by ¹H/¹H NOESY methods in combination with molecular modeling.^{241,242} Frequently, the results obtained on the free oligosaccharides have been compared to those obtained by examinations of the intact glycolipids in DMSO solutions and other aprotic solvents.^{51,55–57,64,187,188,243–247} In particular, the study of peripheral blood group elements which are so abundant on glycolipids features prominently in this work; not unexpectedly (see Section 4.3.1), the conformations of these epitopes are independent of the solvent. Although the results of these studies in DMSO are interesting from a basic science point of view, we will not review their details because of their relative lack of biological significance. Instead, we will turn to micellar systems formed by glycolipids in aqueous solutions (Section 5.2), emulating the cell’s plasma membrane, and compare the carbohydrate’s structures under those circumstances to the structures of the free glycolipid oligosaccharides in water.

Due to the relative ease with which they can be ^{13}C -enriched, glycolipids have recently inspired the development of several new NMR spectroscopic techniques. Heteronuclear 3D NMR experiments, employing ^{13}C chemical shift editing of homonuclear correlation spectra, are an effective means of reducing spectral overlap for larger carbohydrates, particularly when ^{13}C -enriched carbohydrates are available for investigation.^{235,248} Complete ^1H assignments for uniformly ^{13}C -labeled carbohydrates have been obtained with the use of HCCH-COSY and HCCH-TOCSY experiments.²⁴⁹ By employing the $^{13}\text{C},^{13}\text{C}$ coupling pathway [$^1J(\text{C},\text{C}) \sim 40\text{ Hz}$] for magnetization transfer, these techniques overcome the T_2 relaxation [$^3J(\text{H},\text{H}) \ll \text{linewidth}$] problems observed in $^3J(\text{H},\text{H})$ -mediated $^1\text{H},^1\text{H}$ COSY and TOCSY spectra of glycoconjugates of high molecular weights and yield well-resolved spectra for polysaccharides and glycolipids. The 2D constant evolution time HCCH-COSY and HCCH-TOCSY experiments are particularly useful for the study of carbohydrates due to the relatively constant value of $^1J(\text{C},\text{C})$ couplings around the carbohydrate ring (36–45 Hz) which facilitates optimization of the fixed delay for $^{13}\text{C},^{13}\text{C}$ magnetization transfer. The resulting $^{13}\text{C},^{13}\text{C}$ decoupling simplifies the analysis of the ^1H spectra as traces in the 2D plots. Alternatively, ^1H -detected $^{13}\text{C},^{13}\text{C}$ COSY experiments may be performed for complete ^1H and ^{13}C assignments of ^{13}C -enriched oligosaccharides (as was illustrated for the uniformly ^{13}C -labeled carbohydrate headgroup in a sulfolipid²⁵⁰). The sensitivity and resolution of the ^1H -detected 3D ^{13}C COSY experiments can be considerably improved by the implementation of pulsed field gradients, as demonstrated for a digalactosyl diacylglyceride which was biosynthetically uniformly ^{13}C -enriched to $\sim 15\%$.²⁵¹

5 THE FUTURE: GLYCOCONJUGATES IN (INTER-)ACTION AT THE MEMBRANE SURFACE

The molecular behavior of an oligosaccharide chain isolated from a glycoprotein or glycolipid differs considerably from the behavior of the chain when bound to a protein or lipid. For example, the molecular motion of a freely tumbling oligosaccharide will be substantially different from that of the same oligosaccharide anchored to a protein backbone and/or in a lipid bilayer. It is quite conceivable that both molecular conformation and internal dynamics are affected upon the covalent binding of an oligosaccharide to a protein. Thus, appropriate caution must be exercised when extrapolating NMR-derived results concerning conformation and dynamics of isolated oligosaccharides to similar structures linked to proteins or lipids. NMR efforts are now underway to examine the conformation and dynamics of oligosaccharides as covalent parts of larger molecular weight glycoconjugates, both intact glycoproteins (Section 5.1) and glycolipids dispersed in lipid bilayers (Section 5.2). Also, the study of noncovalent carbohydrate-protein interactions via NMR methods is producing its first encouraging results (Section 5.3).

5.1 Glycoproteins

It has been known for quite some time²⁵² that the ^{13}C NMR spectra of intact glycoproteins in solution display signals arising from the oligosaccharide component that are considerably

sharper than those arising from the polypeptide backbone. This observation suggests that the oligosaccharides of at least some intact glycoproteins possess motional characteristics other than those conferred on them by the tumbling of the protein; in other words, local (segmental) motion is experienced by the oligosaccharide chain. In 1982, Goux et al.²⁵³ reported on ovalbumin in which nonreducing Gal was enriched in ^{13}C . Off-resonance rotating frame relaxation data showed that the carbohydrate had a 40–80 ps motion superimposed on the slow overall tumbling ($\tau_o \sim 25\text{ ns}$) of the protein.

Several NMR studies are currently being designed to elucidate the conformational effects of covalently linked carbohydrates on peptides in glycoproteins and vice versa. The glycoprotein ribonuclease B (RNase B) has most often served as the ‘guinea pig’. The consensus with regard to this glycoprotein and several others seems to be that oligosaccharide and peptide do not mutually affect each other’s conformation; instead, the oligosaccharide causes a decrease in the peptide’s conformational mobility near the glycosylation site and vice versa. Thus, mutual effects have been observed on the local dynamics of peptide and oligosaccharide rather than on their conformation per se. For example, NMR measurements of amide H/D exchange rates on RNase A and B revealed that glycosylation of the protein leads to the protection of amide proton resonances from solvent exchange for a large number of amino acid residues in the vicinity of the glycosylation site and in more remote locations.^{254,255} The detailed influence of a high-mannose oligosaccharide on the enzyme’s properties was also explored with a combination of MD simulations of the carbohydrate, employing a novel force field parameterization for glycoproteins (GLYCAM-93), and structural model building based on the 2.5 Å X-ray crystal structure of the enzyme;²⁵⁶ the results are currently awaiting NMR experimental verification.

Studies^{108,231} focusing on the local dynamics of the $\text{Man}_5\text{GlcNAc}_2$ carbohydrate chain in RNase B took advantage of the protein’s presence; the protein is, in essence, a large mass which, relative to the timescale of the internal motions, tethers the reducing end of the glycan. This causes the relaxation parameters to become much more sensitive to differential motion along the glycan chain. In addition, the overall motion of the glycoprotein can be considered to be isotropic, considerably simplifying data analysis. The order parameter S^2 was measured for reorientation of the C-1–H-1 vector of each glycosyl residue. As computed from ^{13}C T_1 values, S^2 was found to be ~ 0.5 for internal residues and ~ 0.1 for terminal residues (most distal to the protein). The rate of internal motion was found to be an order of magnitude higher for the distal than for the proximal residues. These data strongly support the existence of significant torsional oscillations about glycosidic bonds in high-mannose oligosaccharides.

However, there is at least one well-characterized glycoprotein in which carbohydrate and protein conformation do affect each other considerably: the F_c fragment of immunoglobulin G (IgG) containing an *N*-linked carbohydrate chain at Asn₂₉₇ in the hinge region. There is compelling evidence, both from X-ray structural data and molecular modeling,^{77,257} that the (1→6)-arm of the diantennary oligosaccharide interacts with Phe₂₄₃, Pro₂₄₄, and Thr₂₆₀ residues of the protein. These interactions result not only in the loss of the flexibility associated with the (1→6)-arm, but also in a conformation of the

diantenna very different from that of the free oligosaccharide in solution. Recently, the F_c fragment in which ^{13}C -labeled Gal had been biosynthetically incorporated in terminal position of both arms of the diantenna in a similar way to the aforementioned studies on ovalbumin, was probed by ^1H -detected ^{13}C , ^1H NMR. The two Gal residues were distinctly different in their NMR parameters (chemical shifts, linewidth), providing evidence for the strong interaction in solution of one arm of the diantenna with the peptide backbone.

5.2 Dynamics of Membrane-Bound Carbohydrates

Due to their amphipathic nature, isolated glycolipids aggregate in aqueous solution to form micelles. With their long overall rotational correlation times, these systems lend themselves to high-resolution NMR studies and are the most revealing probes currently used for the study of internal motions in lipid-linked oligosaccharides. Poppe and co-workers have studied the conformation and dynamics of the carbohydrate headgroups of a number of glycolipids inserted in deuterated dodecylphosphocholine (DPC) micelles in D_2O and/or H_2O , including globoside,^{129,187} Forssman antigen,¹⁶² and the gangliosides GM_4 ,²⁵⁸ GM_3 and Neu4Ac5Gc-GM_3 ,²⁵⁹ GM_1 ,¹⁸⁸ and GD_{1a} .²⁶⁰ The researchers typically measured interglycosidic $^1\text{H}/^1\text{H}$ NOEs and used these to build tentative 3D structures of the oligosaccharide using a distance mapping procedure.¹⁸⁸ Figure 20 shows 1D NOESY spectra for one of the galactose residues in the GD_{1a} ganglioside/micelle system in D_2O solution. Selective spin locking during the mixing time, obtained with a double-DANTE pulse sequence,²⁶¹ allowed the calculation of, for example, the intraring Gal H-1–H-4 distance based upon a spin-diffusion-free NOE effect.

Figure 21 shows that GD_{1a} in a micellar membrane in H_2O is singularly suited for high-resolution NMR studies, particularly those focusing on its OH signals at low temperature, without the use of organic solvents. It appeared²⁶⁰ that the observed NOEs could not be explained by the occurrence of the GD_{1a} oligosaccharide in a single conformation such as the reasonably rigid structures proposed for the GD_{1a} -free oligosaccharide²⁴² in D_2O and glycolipid²⁴⁵ in DMSO on the basis of ^{13}C T_1 data. At least two families of carbohydrate conformers, differing in the relative orientation of the $\text{Neu5Ac}\alpha(2\rightarrow3)\text{Gal}\beta(1\rightarrow3)$ external disaccharide arm, must exist in this model membrane system to account for the NOE constraints. The internal dynamics of the oligosaccharide were probed by ^1H detection of the ^{13}C relaxation parameters (T_1 , $T_{1\rho}$, and heteronuclear NOEs) of the micellar system at ^{13}C natural abundance. The internal reorientations were found to occur with a rotation correlation time of 0.35 ns. The slow tumbling of the micelle ($M_r \sim 8\text{ kDa}$) provided the distinct timescale ($\tau_o = 2.8\text{ ns}$), facilitating the discovery of the faster internal motion of two flexible glycosidic linkages in the carbohydrate headgroup.²⁶⁰

Applications of these methods to larger complex oligosaccharides, as well as to those tethered to proteins or lipid membranes, will continue to provide valuable evidence with which to address the question of internal motions on a timescale of the reciprocal of the NMR frequency range used in the experiment (0.1–1 ns). Motions on a slower timescale, which would not be detectable by ^{13}C T_1 experiments, can be studied with rotating frame relaxation data ($T_{1\rho}$). With control of the spin

Figure 20 1D NOESY spectra (600 MHz, 25 °C) of $\text{GD}_{1a}/\text{DPC-}d_{38}$ micelles in D_2O solution. Mixing time 0.4 s. (a) Selective irradiation of Gal^3 H-1. The labels indicate intraresidue NOEs that are significantly compromised by spin diffusion. (b) Selective irradiation of Gal^3 H-1 with double-selective spin locking of Gal^3 H-3 and H-5 during the mixing time. The resulting H-1/H-4 NOE intensity is devoid of indirect magnetization transfers

locking field strength, the latter parameter can reveal motions on the μs timescale.

Alternative approaches to unmasking the conformation and dynamics of glycolipids embedded in model membranes include the study of the angular dependence of NOE in oriented systems of GM_3 ganglioside with partially ^{13}C -labeled sialic acid²⁶² at the surface of magnetically oriented membranes. Dipolar interactions measured between ^{13}C , ^{13}C and ^{13}C , ^1H pairs located in the ^{13}C -labeled sialic acid moiety of GM_3 are interpreted as indications that the GM_3 structure is well extended from the membrane surface. In fact, membrane-bound GM_3 was shown to bind wheat germ agglutinin (WGA), leading to the conclusion that the dominant GM_3 structure at the membrane surface is favored for binding by the lectin. These and other aspects of NMR studies of glycolipids at model membrane surfaces are covered in detail by Jarrell (*Glycolipids*) in this Encyclopedia.

5.3 Carbohydrate–Protein Interactions

The general argument made in Section 2 for the role of complex carbohydrates as informational macromolecules implies that there must be a mechanism for decoding the information which is stored in their structures. Apparently, this decoding depends on a group of multivalent carbohydrate-binding proteins known as (se)lectins. Lectins are widely distributed in animal tissues (albeit in small quantities) and bind simultaneously to at least two carbohydrate determinants (epitopes). Some lectins are membrane-bound, others are soluble; both are thought to function by facilitating communication between

Figure 21 ^1H NMR spectra of $\text{GD}_{1a}/\text{DPC}-d_{38}$ micelles in aqueous solutions; (bottom trace) spectrum in D_2O at 22°C ; (top trace) spectrum in 90% $\text{H}_2\text{O}/10\%$ D_2O at 0°C , obtained with the 1–1 echo water suppression technique. The experimental data obtained on the micellar GD_{1a} system are compatible with the existence of two conformations of the external Neu5Ac–Gal portion of the oligosaccharide relative to the core tetrasaccharide anchored into the micelle. Interconversion between the two conformers is fast ($\tau_i = 0.35$ ns; $S^2 = 0.55$ for the external disaccharide unit) relative to the overall tumbling of the micellar system ($M_r \sim 8$ kDa; $\tau_o = 2.8$ ns; $S^2 = 1$)²⁶⁰

cells by linking them together. Antibodies are another class of soluble proteins involved in biological interactions with carbohydrates.

NMR spectroscopy is beginning to emerge as an experimental approach to the study of carbohydrate–protein interactions. Although limited by the size (molecular weight) and solubility of the protein, NMR spectroscopy is particularly useful for detailed studies of protein–carbohydrate interactions in solution when the complex has a molecular weight less than 35 kDa; under favorable circumstances, NMR can provide information about larger molecular weight systems as well. In general, if detailed information about conformation is sought, it is preferable that the ligand or the protein be ^{15}N , ^{13}C and ^{13}C , ^{15}N doubly labeled in order to provide a sufficient amount of structural constraints. For the larger M_r protein–carbohydrate complexes this is a necessity; for the smaller M_r complexes it is highly desirable (cf. Otting²⁶³).

NMR spectroscopic studies on the interactions between proteins and carbohydrates have focused on several systems, including the lectins wheat germ agglutinin^{264,265}, concanavalin A, *Sambucus nigra* agglutinin, *Ricinus communis* B,¹²² and *Aleuria aurantia* agglutinin²⁶⁶ with their respective ligands, and several monoclonal antibodies with their oligosaccharide antigenic counterparts.^{267–269} The typically weak carbohydrate–protein binding and intermediate-to-fast exchange between the free and the bound ligand permit transferred NOE (TrNOE) studies^{108,263,270,271} and lineshape analysis. The aim of a TrNOE experiment is to measure *negative*

Figure 22 (a) The 500 MHz ^1H NMR spectrum of sialyl- $\alpha(2\rightarrow3)$ -lactose [5 mM in $\text{H}_2\text{O}/(\text{CD}_3)_2\text{CO}$, 8:1, v/v] obtained at -12°C with the 1–1 echo water suppression technique. Among the OH signals, the Neu5Ac OH-8 signal is characterized by the smallest exchange contribution to the linewidth and the smallest temperature variation of chemical shift (~ 0.001 ppm $^\circ\text{C}^{-1}$). (b) 1D pre-steady-state NOE difference spectrum obtained subsequent to presaturation of OH-8 under the conditions described in (a); a strong NOE contact to Neu5Ac H-6 is observed. (c) 1D clean-ROESY²⁷² spectrum of sialyl- $\alpha(2\rightarrow3)$ -lactose (5 mM in D_2O , 25°C , 600 MHz). (d) 1D transferred NOESY spectrum of sialyl- $\alpha(2\rightarrow3)$ -lactose in complex with wheat germ agglutinin (4 mM trisaccharide; 0.08 mM WGA; pD = 7, D_2O , 25°C , 600 MHz). Note the absence of an NOE between GalH-3 and Neu5Ac H-3ax in trace (d) while Neu5Ac H-8 experiences a NOE, suggesting that the conformation of sialyl- $\alpha(2\rightarrow3)$ -lactose that binds to WGA is the less populated¹²⁹ conformation free in solution (conformation B; middle right)

NOEs on easily detectable free or averaged carbohydrate resonances following the irradiation of other carbohydrate resonances in order to obtain conformational information on the bound ligand. The true advantage of studying TrNOEs is that the effect is not restricted by the M_r value of the complex; instead, it continues to be favorable as the protein size increases. The TrNOE experiment is one of the few experiments capable of yielding information on the conformation of bound ligands in complex with large-size proteins. In general, the amount of information gained about the system will not be as large as from ^{13}C -labeled systems in the tight-binding/slow-exchange regime, and extreme care must be given to the analysis of the NOE-derived distances. For exchange rates $>100\text{ s}^{-1}$, one can analyze the data with relative ease; for rates between $10\text{--}100\text{ s}^{-1}$, the use of an extended relaxation matrix is necessary, as was demonstrated for the analysis of the binding of β -methylmelibiose to ricin B.¹²² The lectin preferentially selects one of the two conformations that melibiose adopts when free in solution. Similarly, WGA preferentially binds one of the two major conformations that sialyl- $\alpha(2\rightarrow3)$ -lactose adopts around the Neu5Ac-Gal linkage when free in solution. A preliminary TrNOE study of WGA isolectin 1 in complex with sialyl- $\alpha(2\rightarrow3)$ -lactose (Figure 22) suggests that conformation B is the one which preferentially binds to the lectin, in accordance with the crystal structure of the complex of WGA isolectin 1 with sialyl- $\alpha(2\rightarrow3)$ -lactose.²⁷³ More detailed studies are in progress to confirm this hypothesis. The studies follow the protocol of a recent NMR and X-ray study of the complex of a monoclonal antibody with a branched trisaccharide epitope.²⁶⁹ For this complex, Bundle and co-workers measured NOE build-up rates from TrNOE experiments which show that the trisaccharide undergoes a protein-induced conformational shift around a specific glycosidic linkage when bound in solution. Distance constraints derived from the TrNOE studies are consistent with two bound trisaccharide conformations, one of which correlates with the ligand conformation in the crystalline trisaccharide-antibody complex.

6 CONCLUSIONS

Since its first application to monosaccharide derivatives in the late 1950s, NMR spectroscopy has greatly contributed to our current knowledge of the structures and functions of complex carbohydrates. The importance of oligosaccharides in their own right and as the 'business ends' of glycoconjugates are becoming increasingly appreciated, and the role that NMR has played in this accomplishment cannot easily be overestimated. First of all, NMR spectroscopy provides a powerful nondestructive means with which to characterize the primary structures of carbohydrates and has, therefore, become an integral part of the current methodology of protein glycosylation site mapping. Moreover, the vast potential of NMR to unravel 3D carbohydrate structures and dynamics, as well as to study carbohydrate-protein interactions, is just beginning to penetrate into the collective mind of the glycobiology community. At the same time, NMR spectroscopists long preoccupied with the study of protein-peptide and protein-nucleic acid interactions are beginning to see the merits of investigating protein-carbohydrate interactions. Biological data point to a pivotal function for glycoproteins in the control of growth and

differentiation in the complex cell organization of eukaryotic systems. In fact, some complex oligosaccharides are implicated as onco-fetal antigens. Thus, the biological function of the complex carbohydrate chains of glycoproteins and glycolipids in animals is perhaps one of the most interesting unanswered fundamental questions in modern biochemistry. Unmasking carbohydrate structure-function relationships has been marked as the next frontier in molecular biology; the glycobiology community now finds itself turning to NMR spectroscopy to provide the instrumental means with which to enter this 'promised land'.
